Since the beginning of the 1960s, high-resolution \( \gamma \)-ray spectrometry developed dramatically with the introduction of the Ge-based semiconductor detector, the multichannel analyzer and, somewhat later, the computer. In activation analysis, multielement analysis frequently can be performed easily without chemical separation. PAA has been extensively applied to a large variety of materials as a complementary tool for NAA, and it has been recognized that PAA is suitable for multielement analysis of geological, biological and environmental materials. The analysis of light elements in highly purified materials has been also very important in the field of material science and technology and will be of urgent interest also in the future.
Electron accelerators of comparatively low energy (a few tens of mega-electron-volts) and high power (a few kilowatts) have been used for PAA. However, a limited number of electron accelerators suitable for PAA are available for analysts since modern accelerators are designed for the production of much higher energies to primarily meet the demands of nuclear and particle physicists.

1.4 Textbook and Data Collections for Photon Activation Analysis

In 1972, Engelmann\(^6\) introduced PAA in his book *Advances in Activation Analysis*, in which the principle of PAA and the application to light element analysis were explained in detail. *Photon Activation Analysis* by Segebade et al.\(^7\) is a comprehensive textbook of PAA, containing 1206 references and many useful tables, such as a list of usable and competing photonuclear reactions and a list of \(\gamma\)-rays and X-rays. Kushelevsky\(^8\) presented a short guide of PAA in *Activation Analysis*, where the principles and applications of the method are concisely summarized.

Toms\(^9\) compiled the photonuclear reaction products and their \(\gamma\)-ray energies whilst Williams et al.\(^{10,11}\) collected \(\gamma\)-ray spectra of 40–44 MeV photon activation products. Lutz and Segebade\(^{12}\) published a two-dimensional (half-life versus \(\gamma\)-ray energy) map of photonuclear reaction products and Kato\(^{13}\) obtained sensitivities of 71 elements in PAA using 30 MeV bremsstrahlung. These basic data have been very helpful for users of PAA.

2 PHOTONUCLEAR REACTION

2.1 Characteristics of Photonuclear Reactions

A photonuclear reaction is the interaction between a nucleus and photon. The cross-section of a photonuclear reaction is mainly dependent on the probability of photon absorption. A schematic representation of the cross-section of the photon absorption is shown in Figure 1.\(^7\)

The inelastic reaction which is expressed by \((\gamma,\gamma')\) can be induced by the irradiation of photon energies even below a few mega-electron volts and target nuclides are excited from the ground state to some isomer levels. The cross-section integrals of \((\gamma,\gamma')\) reactions are very small, and only a few radioisotopes which are useful for PAA are produced. A photonuclear reaction is usually characterized by the “giant dipole resonance” or “giant resonance”, because this type of reaction has the largest cross-section among several types of photonuclear reactions. When the wavelength of the photon becomes similar to the diameter of nucleus, the photon can be absorbed by the target nucleus through the electric dipole resonance mechanism with a high degree of probability. This phenomenon is interpreted by the fact that a collective oscillation of all protons against all neutrons is induced by the electromagnetic wave. The maximum cross-section region is located at about 14 MeV for heavy elements to about 25 MeV for light elements. After photon absorption, one or two neutrons and/or protons or higher-order particles can be released because the binding energy of one nucleon is about 10 MeV. At about 60 MeV where the wavelength approximately equals the diameter of the deuteron, a neutron–proton pair in a nucleus is likely to absorb the photon. As the result of this reaction, called a “quasi-deuteron reaction”, a proton and neutron pair is emitted. In this energy region, two or more nucleons can also be released from the target nucleus by a direct process and many kinds of reaction products are formed. The cross-sections of the direct process are much smaller than that of the \((\gamma,n)\) reaction of the giant resonance region. Above 150 MeV, the total photoabsorption cross-section increases again because of the photo-meson production. As the spallation and fragmentation reactions are also induced, various reaction products are produced. However, the latter two types of photoreaction are not suitable for analytical purposes, but rather have to be considered as sources of interference.

2.2 Bremsstrahlung for Photon Activation

Several radioisotopes (e.g. \(^{124}\)Sb) were used as \(\gamma\)-ray excitation sources and applied to the analysis of deuterium, beryllium and several isomeric states. Photon fluxes from...
such radioisotopes are usually not sufficient for practical elemental analysis purposes.

Bremsstrahlung is used preferably for activation in PAA. Bethe and Heitler\(^{(14)}\) theoretically discussed the radiation loss of electrons. Interaction between electrons and matter can be explained as follows. For low atomic number \((Z)\) target material and low-energy electrons, the major partition of energy loss is due to ionization. For high-

\[ Z \] target and high-energy electron, radiation energy loss is increased. As the radiation loss is proportional to \(Z^2\), elements with higher atomic number more efficiently produce bremsstrahlung. Radiation length is defined as the thickness in which the energy of the electron is reduced to \(1/e\) of its incident energy. The radiation lengths of air, aluminum and lead are 304 m (36.7 g cm\(^{-2}\)), 8.9 cm (24.0 g cm\(^{-2}\)) and 5.6 mm (6.37 g cm\(^{-2}\)) respectively. The cross-sections of ionization and radiation loss become equal at a critical energy which is about 800/Z MeV, where \(Z\) is the atomic number of the target. Therefore radiation loss becomes predominant for electrons above 10 MeV, when a heavy element, e.g. platinum, is used as target material.

In the case of a thin target, bremsstrahlung is radiated strongly to the forward direction, i.e. the direction of the incident electron beam. A thick target is used in practice for activation analysis. In this case, the angular distribution of bremsstrahlung is broadened, and the percentage of low-energy photons increases because of the multiple scattering of the electron in a thick target. Figure 2 shows the calculated photon flux for electron energies of 25, 30 and 35 MeV and a mean electron beam current of 100 \(\mu\text{A}\).\(^{(15)}\) The spectrum of bremsstrahlung is calculated by Schiff’s equation.\(^{(16)}\) The tungsten target is 6 mm (two radiation lengths) thick, which is the range of 35 MeV electrons (thus, all incident electrons are absorbed). The spectrum is integrated over 5\(^{\circ}\) from the direction of the electron beam.

In PAA, the most suitable irradiation energy is 20–30 MeV because the radiated bremsstrahlung spectrum covers the giant resonance region of most of the nuclides. Under such irradiation conditions, reaction products induced by the \((\gamma,n)\) and \((\gamma,p)\) reactions can be conveniently used for quantitative element determination.

### 2.3 Photonuclear Reaction Yield

In PAA, the reaction yield is used for the estimation of sensitivity of the pertinent element and the magnitude of nuclear interference. When a photonuclear reaction is induced by the irradiation of bremsstrahlung of a certain maximum energy the photonuclear reaction yield \(Y\) can be derived by the integral in Equation (1) by using the bremsstrahlung spectrum and the excitation function for the relevant reaction,

\[
Y = N_0 \int_{E_{th}}^{E_{max}} \sigma(k) \Phi(k, E_{max}) k^{-1} dk \tag{1}
\]

where \(N_0\) is Avogadro’s number, \(E_{th}\) is the threshold energy for the reaction, \(E_{max}\) is the bremsstrahlung maximum energy, \(\sigma(k)\) is the cross-section in square centimeters per nucleus, and \(\Phi(k, E_{max})/k\) is the number of photons at a given energy \(k\). If the bremsstrahlung spectrum is normalized to 1 roentgen and a target amount of 1 mole is used, a yield can be obtained per mole per roentgen.

When equivalent quanta, \(Q\), are introduced, the yield per equivalent quanta for the given reaction, \(\sigma_Q\), is given by Equation (2),

\[
\sigma_Q = Q^{-1} \int_{E_{th}}^{E_{max}} \sigma(k) \Phi(k, E_{max}) k^{-1} dk \tag{2}
\]

where \(Q\) is given by

\[
Q = \int_{0}^{E_{max}} \Phi(k, E_{max}) dk \tag{3}
\]
According to the definition, \( Q \) is a hypothetical number of photons per second per square centimeter assuming maximum energy of all photons.

The general feature of a photonuclear reaction yield at the bremsstrahlung maximum energy of 30 MeV is shown in Figure 3 where the yields of various types of photonuclear reactions are plotted against the atomic number.\(^{13}\) The yields (mol\(^{-1}\) R\(^{-1}\)) of \((\gamma,n)\), \((\gamma,2n)\) and \((\gamma,3n)\) reactions increase with mass number. The \((\gamma,2n)\) reaction yield is about one order of magnitude smaller than that of \((\gamma,n)\) reaction for heavy elements. The \((\gamma,p)\) reaction shows maximum yield at atomic number 20 and decreases with atomic number. In the case of higher-order charged particle emission reaction, yield curves show a similar shape as that of \((\gamma,p)\) reaction.

The reaction yields of the \((\gamma,n)\), \((\gamma,p)\) and \((\gamma,\alpha)\) reactions were measured with 20 MeV bremsstrahlung irradiation. The difference of the yields between 20 and 30 MeV are small. The reaction yields were also measured systematically at 60 MeV irradiation.\(^{19}\) The yields of the single particle emission reactions, such as \((\gamma,n)\), \((\gamma,p)\) and \((\gamma,\alpha)\), are almost equal to the results of 30 MeV irradiation. The yields of \((\gamma,2n)\), \((\gamma,3n)\), \((\gamma,4n)\), \((\gamma,\alpha n)\) and \((\gamma,\alpha\alpha)\) reactions are remarkably higher. The \((\gamma,2p)\) reactions are observed for several light elements. The emission of more particles, up to nine, was observed at 60 MeV.

To observe the dependency of the photonuclear reaction yield upon energy and mass number, the functions of the yield \((Q_\gamma; mb)\) for the \((\gamma,n)\), \((\gamma,p)\) and \((\gamma,\alpha)\) reactions are shown in the form of two-dimensional graphs in Figures 4, 5 and 6. In these figures, \(x\)- and \(y\)- axes show the target mass number and bremsstrahlung energy.
PHOTON ACTIVATION ANALYSIS

3 ANALYTICAL APPLICATION OF PHOTON ACTIVATION

3.1 Conditions of Photon Activation Analysis

At constant photon flux during irradiation, radioactivity induced in an element to be determined can be calculated as shown in Equation (4):

$$A = \frac{wN\theta}{AW} \sigma Q \left[1 - \exp(-\lambda t)\right]$$

(4)

where $w$ is the amount of element, $\theta$ is the isotopic abundance of the target isotope, $AW$ is the relative atomic mass of element, $\sigma Q$ is the yield (cm$^2$ per equivalent quanta), $Q$ is the flux density (equivalent quanta cm$^{-2}$s$^{-1}$), $\lambda$ is the decay constant of the induced radioisotope, and $t$ is the irradiation time.

In order to produce bremsstrahlung efficiently, metals of high $Z$ and high melting point, such as platinum and tungsten, are recommended as a converter material. Electron energy which is higher than about 15 MeV is indispensable to induce giant resonance reactions. Beam currents of several tens to hundreds of microamperes are necessary to induce radioactivity giving sufficient detection sensitivity. Betatrons and synchrotrons are not suitable for PAA due to their low beam currents. In Van de Graaf accelerators, beam current is in the microampere region, but the acceleration energy is low. However, many types of electron linear accelerators and microtrons are suitable for PAA.

As an example, consider the induced radioactivity estimated using Equation (1). The equivalent quanta obtained under the irradiation conditions mentioned above are about $10^{14}$ cm$^{-2}$ s$^{-1}$. The yield of $(\gamma,n)$ reaction is around 100 mb ($10^{-25}$ cm$^2$) for elements in the relative atomic mass region of around 100 (say molybdenum through silver). When 1 $\mu$g$^{-1}$ of an element in a sample of 100 mg is analyzed, the number of target nuclides is about $10^{14}$. After irradiation for a duration equal to 1/10 of the half-life of the radioisotope, induced activity is about $10^3$ disintegrations s$^{-1}$. When the detection efficiency is 1%, 10 counts s$^{-1}$ can be obtained. To obtain $\gamma$-ray peak counts within a counting error of 1%, a counting time of 1000 s is necessary at least. Therefore, it seems to be efficient to simply increase the irradiation time, flux, sample mass, detector efficiency and counting time. However, in the instrumental approach (analysis without radiochemical separation), the detection limit cannot always be improved so simply since the background activity might also be increased. The choice of irradiation energy and the cooling time is more effective to attain better detection limits.

Sensitivity data have been published which were obtained for several conditions of irradiation and

maximum energy, respectively. In each figure, function graphs of the respective reaction yields are drawn. The yield “zero” marks the calculated mass threshold.

The $(\gamma,\text{n})$ reactions start to take place in the 10 MeV region, and the yield increases rapidly with energy up to 30 MeV. The curves are relatively parallel to the energy axis above 30 MeV. It is found that the yield is dependent on the mass number rather than on the excitation energy in this energy region.

The charged particle emission reactions such as $(\gamma,p)$ and $(\gamma,\text{pn})$ show quite different behavior. The functions run through a maximum for mass numbers between 50 and 60. The reaction yields decrease with increasing mass number at the given bremsstrahlung maximum energy. This is due to the Coulomb potential barrier restriction of high-Z nuclei. Below 50 MeV, the yield of certain mass numbers is dependent on the bremsstrahlung maximum energy. The yield of the $(\gamma,\text{pn})$ reactions shows similar patterns to that of the $(\gamma,p)$ reactions though the former have higher threshold and lower yields than the latter.

Similar charts of photonuclear reaction cross-section and the trends of integrated cross-section were also given by Barbier. He also applied the simple calculation method of induced activity. The excitation curves for the photofission reaction, the photoproduction of $\pi$-mesons and other various reactions up to the gigaelectron-volt region are shown in this paper.

The $(\gamma,\text{n})$ reaction is useful for the determination of light to heavy elements and the $(\gamma,p)$ reaction is favorable for the analysis of medium-Z (from Na up to Sn) elements.

![Graph](image.png)

**Figure 6** Yields of the $(\gamma,\text{pn})$ reactions as a function of bremsstrahlung maximum energy and target mass number. The numerical values in the figure are yields per equivalent quanta (in mb). (Reproduced from K. Masumoto, T. Kato, N. Suzuki, 'Activation Yield Curves of Photonuclear Reactions for Multielement Photon Activation Analysis', Nucl. Instrum. Methods, 157, 573 (1978) by permission of North-Holland Publishing Co.)
measurement, e.g. irradiation energies of 20 MeV, (17) 30 MeV, (13) 40–44 MeV (23) and 110 MeV. (24) Lutz calculated sensitivities for electron energies of 25, 30 and 35 MeV. (15)

3.2 Characteristics of Photon Activation Analysis

Since PAA is a complementary method to the more familiar NAA, the characteristics of both are compared in the following.

3.2.1 Transmittance of High-energy Photons

As high-energy photons can penetrate and activate mostly without notable matrix effects, PAA is suitable for bulk analysis of various kinds of materials and for simultaneous irradiation of several samples. The photon flux decreases with distance from the conversion target. Moreover, the bremsstrahlung beam exhibits a sharp flux density gradient perpendicular to the beam axis. Thus the activating radiation doses of samples and comparison standards should be monitored.

3.2.2 Systematic Trend of Photonuclear Reaction Yields

The (γ,n) reactions are mostly utilized in PAA. As shown in Figures 3 and 4, the threshold energies of the (γ,n) reactions are about 10 MeV for heavy elements and about 20 MeV for light elements. The (γ,n) reaction yields of heavy elements are up to two orders of magnitude higher than those of light elements at the bremsstrahlung maximum energy of 30 MeV. However, light elements are usually major components and heavy elements exist at trace levels in natural products. As the radioactivity induced in an element is roughly proportional to the product of the yield and the abundance of the pertinent element, the differences in radioactivities induced in the light and heavy element fractions are frequently of the same order of magnitude. Such a systematic trend of photonuclear reaction yields gives the well-balanced sensitivities for the instrumental analysis of natural samples.

3.2.3 Interference by Self-shielding Effect, Matrix Activity and Fission Products

In NAA, the self-shielding effect and intense radioactivity sometimes interfere with trace element analysis, as there are several nuclides which have anomalously large neutron capture cross-sections. Typical examples of self-shielding are Cd and B. In NAA, after neutron exposure, 32Na, 32P and 82Br are major activities in biological materials and 56Mn and 24Na are major activities in rock, dust, soil and related samples because of their large neutron activation cross-sections. Rare-earth metals such as Eu and transition metals such as Co also lead to intense radioactivities and self-shielding. In PAA, such a self-shielding effect is mostly negligible, and the problem of matrix activity is not so frequent because of the penetrability of bremsstrahlung and, respectively, the systematic character of photonuclear reaction yields as mentioned above.

When U and/or Th are present in a sample in large amounts, neutron-induced fission products often interfere with the analysis of medium to heavy elements because the radioactivities from light elements are roughly proportional to the activation cross-section and the abundance of the pertinent element. However, these elements are easily determined by PAA because the photonuclear reaction products of these elements have suitable nuclear characteristics for photon spectrometry. More than 30 elements in geological and environmental samples can be determined instrumentally. To reduce radioactivities from light elements and to improve the signal-to-background ratio for heavy elements, 20 MeV irradiation is sometimes preferable to 30 MeV irradiation. Most of the medium to heavy elements can be determined at concentration levels of micrograms per gram and below.

3.2.4 Characteristics of the (γ,n) Reaction Products

Radioisotopes induced by the (γ,n) reaction decay with positron emission and/or EC in the most cases. Several light elements, such as carbon, nitrogen, oxygen and fluorine, lead to purely positron-emitting nuclides. These can be determined by the coincidence counting method (see below, section 4.1). Many of the (γ,n) products from medium to heavy elements decay by EC. In EC decay, the detection of characteristic X-rays of the decay product is convenient for analytical purposes. Low-energy photon spectrometers (see above) are useful to detect characteristic X-rays and low-energy γ-rays.

4 ANALYTICAL PROCEDURES

4.1 Procedure for Light-element Analysis

As mentioned above, the photonuclear activation products of some light elements like C, N, O and F are pure positron emitters without any characteristic photon emission. The annihilation photon quanta (E = 511 keV) produced through reaction of positrons with electrons in close vicinity can be measured most favorably with a pair of γ-ray detectors facing one another and electronically switched in coincidence. (6,7) Since the annihilation
PHOTON ACTIVATION ANALYSIS

4.2 Procedure for Multielement Analysis

Multielement analysis of natural samples by the comparative method is described as a typical case of PAA. The comparative method (see section 4.1) is mostly used in PAA. When a sample is irradiated with a comparative standard that contains \( w_{\text{std}} \) of the element to be determined the unknown amount \( (w_x) \) of element in the sample is obtained by Equation (5):

\[
w_x = w_{\text{std}} \left( \frac{A_x}{A_{\text{std}}} \right) \left( \frac{\phi_{\text{std}}}{\phi_x} \right)
\]

where \( A_x \) and \( A_{\text{std}} \) are the activities induced from the element to be determined and \( \phi_x \) and \( \phi_{\text{std}} \) are fluxes of bremsstrahlung irradiated on the sample and the comparative standard respectively.

Usually, the \( \gamma \)-ray peak area ratio of the sample and the standard is used instead of the activity ratio \( (A_x/A_{\text{std}}) \). In this case, the counting geometry (such as the shapes of sample and standard, the distance from sample and detector) must be equal. As the radioactivity decays according to its half-life after irradiation and also during measurement, the radioactivity of sample and standard should be normalized to the same time, usually the end of irradiation. When the obtained peak count number \( (C) \) is normalized to the end of irradiation, the initial activity \( (A) \) is calculated by Equation (6):

\[
A = \frac{C\lambda}{\exp(-\lambda t_c)[1 - \exp(-\lambda t_m)]}
\]

where \( \lambda \) is the decay constant \([\ln(2)/t_{1/2}]\) for the radioisotope, \( t_c \) is the cooling time after irradiation, and \( t_m \) is the measuring time.

4.3 Sample Preparation, Standard and Flux Monitoring

For the comparative method, a standard containing a well-known amount of each component to be analyzed must be available. This might be a multielement or a single element comparator. It is desirable that such a standard and samples have similar elemental compositions. These materials should be prepared under strictly controlled conditions following preparation procedures which enable maximum accuracy of the respective element concentrations. Certified reference materials (CRMs) should not be used for highly precise concentration calculations, but rather as materials analysed for quality control of the obtained results, the accuracy in particular.

As various kinds of CRMs are issued by many organizations in the world, a standard suitable for nearly each analytical purpose can be chosen. These CRMs are analyzed by several analytical methods at several laboratories. However, most of these certified values are averaged values with standard deviations. Usually only limited numbers of elements are certified. There are several examples where the concentration of the element to be determined is not certified or its concentration is largely different from that in the sample. In order to avoid this, two or more CRMs can be used for cross-checking. When natural products are used as CRMs, homogeneity and stability should be checked carefully. Also limited...
amounts of CRMs have been supplied. In most cases the use of CRMs as comparators is not recommended, since high-precision results as required in certification analyses cannot be expected.

Laboratory standards have been useful to solve the above problems. A filter paper doped with several standard solutions of elements to be determined is often used in NAA. This method cannot be recommended for PAA because a small amount of residual acid might decompose the cellulose paper during irradiation. Moreover, the homogeneity of filter paper is questionable. Phenol–formaldehyde resin and gelatine were used as the base materials for activation analysis of biological materials. An artificial standard of polyacrylamide gel matrix was also developed by utilizing the copolymerization reaction of acrylamide in a mixed solution containing the appropriate amounts of elements. Polyacrylamide has high tolerance for radiation and a similar matrix composition to biological materials. For the analysis of rock samples, multielement solution was gelatinized by hydrolysis of tetraethylsilicate. As the gelatinization takes place in acidic conditions, most of the standard solution of metals can be used directly. Silica gel has high stability for irradiation. The elemental abundance in such synthetic standards is easily and accurately obtained as the weight ratio of the added amount of element to the final weight of gel, and elemental composition can be adjusted freely according to samples to be analyzed and elements to be determined. The homogeneity of these standards is usually satisfactory because the mixed solution containing several elements is solidified as is.

As photon flux and energy spectrum show pronounced gradients, bremsstrahlung irradiated on each sample should be monitored individually. To estimate flux, sample and standard are stacked alternately or irradiated with flux monitors. The accuracy of the former method is good because the specific activity of each element in the standard is plotted against the irradiation position and the specific activity induced in the sample can be estimated. However, the measurement of samples and standards irradiated is very time-consuming. In the latter method, the monitor reaction data are largely different from the reaction for analysis of each element. Therefore, it is recommended to choose the monitor reaction that has a similar excitation function to the reaction for analysis, and a product radioisotope that has a half-life similar to those of the radioisotopes to be determined.

4.4 Irradiation

An example of an irradiation set-up is shown in Figure 7. The beam profile can be observed with a thin beryllium oxide disk of 0.2 mm in thickness and the beam position is precisely adjusted with a platinum position monitor made up of a thin wire and a small flat tip connected to an electronic microammeter. The platinum tip is positively charged by secondary electron emission when hit by the electron beam. Therefore, the beam position can be pointed exactly to the center of sample by scanning for the maximum current of the microammeter. The beam intensity is indirectly monitored with a ferrite-core-loaded toroidal coil coupled with a current integrator after rectification, because electric current is induced on the toroidal coil when a pulsed beam is passing through the core. This core monitor has been calibrated with a pulse generator. The induced pulses are also monitored.
with an oscilloscope. Four pieces of platinum plate of 0.5 mm thickness are placed inside the sample holder to serve as the conversion target. The converter and sample are cooled with water to avoid melting of materials caused by high incident beam power. The beam power, which is the product of electron energy and average beam current, turns to heat finally. In this facility, irradiation, for activation analysis has usually been performed at 30 MeV electron energy and 150 µA average current. Hence, 4.5 kW of beam power is focused within a diameter of a few millimeters.

Bremsstrahlung does not cause such significant radiation damage on the sample. Electrons penetrating the converter cause radiation damage and local heating which creates severe problems especially for biological samples. To reduce effects caused by penetrating electrons, a graphite block has been inserted between the converter and sample. Light elements absorb electrons efficiently without reducing the flux of bremsstrahlung from the converter considerably. Also, a bending magnet placed behind the converter to deflect electrons passing through the converter has been applied. In this case, samples should be kept at a good distance from the converter to avoid unwanted electron bombardment.

Another possibility to avoid electron-induced damage is to use a thick target which absorbs all electrons (see above).

Secondary neutrons are mainly emitted from the converter and also from surrounding materials. These neutrons are predominantly induced by photonuclear reactions in the giant resonance region. It is known that energy spectra of photoneutrons are predicted by the statistical model of the nucleus, and the angular distribution is mainly isotropic. Photoneutrons are retarded by the collision with surrounding materials and thermalized by water and other light material in the vicinity. Such neutrons cause the (n,γ), (n,p) and (n,α) reactions in a sample.

The spatial distributions of bremsstrahlung and photoneutrons are shown in Figure 8. Figure 8 shows the results of Pt (2 mm) plus graphite (10 mm) and Pt (2 mm), W (3 mm) and graphite (10 mm). The solid lines show the distribution of activity of $^{196}$Au induced by the $^{197}$Au(γ,n)$^{196}$Au reaction which corresponds to the flux of bremsstrahlung. In Figure 8, the spatial distribution of neutrons is drawn by dotted lines, according to the $^{198}$Au activity induced by the $^{197}$Au(n,γ)$^{198}$Au reaction. According to the result of Engelmann, the best thickness of

![Figure 8](image-url)
platinum converter to induce \((\gamma,n)\) reactions is 3 g cm\(^{-2}\) at 30 MeV and 4.5 g cm\(^{-2}\) at 45 MeV. As the thickness of 2 mm is 4.3 g cm\(^{-2}\), the converter thickness presented in Figure 8(a) is suitable for activation. In this case, electron energy is reduced by half of the initial energy. The target combination of Figure 8(b) is used for the irradiation of biological materials. The additional converter of 3 mm thick W plate can reduce the initial electron energy by a factor of six, and the graphite block of 10 mm in thickness can fully absorb electrons passing through the converter. As this graphite block absorbs only 3 to 4% of photons at the energy of 10 to 30 MeV, photon flux is not suppressed significantly. As shown in Figure 8(b), the bremsstrahlung beam produced by the converter of 5 mm in thickness is broadened, and the photoneutron flux is increased. The full widths at half-maximum of bremsstrahlung induced by 2- and 5-mm-thick converters are 12 and 16 mm, respectively, directly behind.

the graphite block. Through quasi-elastic scattering the
photoneutrons are also distributed behind the graphite
block. The spatial distribution and neutron thermalization
are influenced by the irradiation conditions. To estimate
the interference caused by photoneutrons it is recom-
mended that neutron monitors be applied adjacent to the
samples during each radiation cycle.

High irradiation energy is preferable to obtain better
sensitivity. However, as several types of photonuclear
reactions are increasingly induced at the incident electron
energy above 30 MeV, nuclear interference problems
arise at higher irradiation energy.

4.5 Measurement and Evaluation

The elements and nuclear data for PAA of typical natu-
ral samples are listed in Table 1. Since each radioisotope
has a specific half-life, detection sensitivity and signal-to-
background ratio, which depend upon both matrix activity
and radioactivity to be analyzed, are strongly decay-time
dependent. Figure 9 shows the time dependency of detec-
tion limits of nine elements in coal fly ash (NIST Standard
Reference Material (SRM) 1633a) irradiated at 25 MeV
for 2 h. The detection limit is defined as the concentra-
tion of element which yields the count number equal to 3σ of
background counts under pertinent γ-ray photopeak. As
shown in Figure 9, the detection limit strongly varies
with cooling time. For multielement analysis of natural
samples, γ-ray spectra of samples should be measured
several times at appropriate intervals after irradiation.
In Figure 10, the detection limits of 26 nuclides are
plotted against a suitable cooling time in the case of coal
fly ash quoted above. The degree of interference from
γ-ray overlapping also changes according to the half-lives
of pertinent nuclides. Therefore, the cooling time should
be carefully adjusted in order to analyze each element
under the best possible conditions.

As a result, typical γ-ray measurements for the analysis
of the type of natural products studies are performed
preferably in the following periods: (1) a few minutes
after irradiation for K, Cl; (2) a few hours after irradiation
for Ti(47Sc), Sc, Fe, Sr; (3) a few days after irradiation
for Mg, Ca(43K), Ti(48Sc), Ni, Ba, Pb; (4) 1 week after
irradiation for Ca(47Ca), Zn(67Cu), Cs, Zr, Mo, Sb, U; and
(5) several weeks after irradiation for Na, Ti(46Sc),
Cr, Mn, Co, Zn(65Zn), As, Rb, Nb, Y, I, Ce, Tl. Two or
more radioisotopes are available for the determination of
several elements, e.g. Ca, Ti and Zn.

5 INTERFERENCE MANAGEMENT

5.1 Interference Reactions

In PAA, a radioisotope used for determination can be produced by another element. The interference reactions have been discussed by Kato et al.,(20,21) Williams and Hislop,(23) Segebade et al.(33) and Miyamoto et al.(34) Typical examples of nuclear interference are listed in Table 2. For example, $^{55}$Mn$(\gamma,n)^{54}$Mn and $^{52}$Cr$(\gamma,n)^{51}$Cr reactions are used for the determination of Mn and Cr. However, $^{54}$Mn and $^{51}$Cr can be produced by $^{56}$Fe$(\gamma,\alpha)n$ $^{54}$Mn and $^{56}$Fe$(\gamma,\alpha)n$ $^{51}$Cr reactions from Fe. The degree of interference is strongly dependent upon the irradiation conditions and, in particular, the Mn/Fe ratios in interference cases caused by photonuclear reactions decrease with the distance from the graphite block. In this interference case, the change of the weight ratio reflects the change of bremsstrahlung spectrum. This is due to the larger scattering cross-section of lower photon energies. In the case of photoneutron interference, the fast neutron flux rapidly decreases with the distance from the converter; consequently, the interference yield by slow neutrons becomes more significant than that by fast neutrons.

The nuclear reaction yields of the analytical reaction and the interference reaction were studied systematically. The results are listed in Table 4 for the SRM orchard leaves (NIST SRM 1571) and in Table 5 for the geochronological interference sample JB-1 (basalt) issued by the Geological Survey of Japan. The magnitude of interference, expressed as the percentage of the activity induced by the interference reaction to the total activity, increases with the irradiation energy.

$^b$ Interference caused by photoneutron.

The use of doublet or multiplet peaks from one product nuclide should also be avoided. Typical examples for peak overlap interference by different nuclides are listed in Table 6. This type of interference mainly occurs during analysis of medium to heavy elements. To avoid the interference, the difference of half-lives of product nuclides can be effectively used in the following cases: Co/Ca, As/Ca, Ti/Zn and Pb/Hg. However, this frequently entails excessive time consumption in the analytical task. On the other hand, if one nuclide emits two or more $\gamma$-ray energies, the peak ratio method can be applied to subtract the interfering peak area. Typical examples are Zn/Ga, Nb/Fe, Cs/I, I/Y and U/Ga. The latter method reduces the time consumption, but a greater analytical error is induced.

Nowadays the $\gamma$-ray overlapping interference is not so problematic due to the dramatic improvement of the energy resolution power of modern photon spectrometers; a modern Ge detector offers peak half-widths of 1.8 keV or less at 1333 keV ($^{57}$Co). Moreover, several highly efficient peak deconvolution programs have been developed.

5.3 Other Errors

As mentioned in section 3.1, the induced radioactivity is proportional not only to sample mass but also to the cross-section and isotopic abundance of the sample components, flux of bremsstrahlung and saturation factor. In the case of $\gamma$-ray measurement, the peak count number obtained is dependent on the counting time, $\gamma$-ray branching ratio of radioisotope, detection efficiency of $\gamma$-ray and others. In the above factors, sample mass, irradiation time and counting period can be adjusted to reduce statistical errors and to improve precision and detection limit. However, the improvement of these factors is often restricted by the experimental conditions, such as number of samples and limited access to irradiation and measurement facilities. It is important to store the peak counts until the counting error becomes small enough.

Activation analysis includes the following steps: (1) sample preparation; (2) irradiation; (3) measurement; and (4) analysis. To improve accuracy, systematic errors...
in each step should be checked carefully. Nuclear interference and \(\gamma\)-ray overlapping are avoidable, but some systematic errors, such as flux monitoring and counting geometry, cannot be cancelled out by quantitative methods. In the following section, the internal standard method, the standard addition method and the stable isotope dilution activation analysis used for highly accurate analyses are described.

6 QUANTITATIVE METHODS FOR QUALITY ASSURANCE

6.1 Internal Standard Method

The most reliable method for monitoring the activating flux received by a sample is the method using an internal standard because the flux monitoring component is inherent in both the sample and the comparative standard. This method was called the internal reference method by Tsai et al.\(^{35}\) and Yagi and Masumoto\(^{36}\) or the internal monitor method by Oka et al.\(^{37}\) in order to differentiate the slight change of the definition of each technique applied.

First, the comparative standard in which the abundance ratio \((K)\) of the element \((a)\) to be determined and the internal standard element \((b)\) are accurately known is prepared. It is not necessary to know the absolute abundance of each element. The accurately weighed amount \((w_b)\) of the internal standard is added to the sample and mixed homogeneously. Then, appropriate amounts of the sample and the comparative standard are irradiated. The activity ratio of a pertinent element to the internal standard is measured for the sample \((R)\) and the comparative standard \((R^*)\), respectively, and the relevant equations are shown as Equations (7) and (8).

\[
R = \frac{A_a}{A_b} = \frac{(w_a N \beta a/AW_a) \sigma_a Q [1 - \exp(-\lambda_a t_a)]}{(w_b N \beta b/AW_b) \sigma_b Q [1 - \exp(-\lambda_b t_b)]} \quad (7)
\]

\[
R^* = \frac{A_a^*}{A_b^*} = \frac{(w_a^* N \beta a/AW_a) \sigma_a Q^* [1 - \exp(-\lambda_a t_a)]}{(w_b^* N \beta b/AW_b) \sigma_b Q^* [1 - \exp(-\lambda_b t_b)]} \quad (8)
\]

The sample weight and flux \((Q)\) are eliminated by introducing the activity ratio. Again, by including the ratio of the two activity ratios \((R^*/R)\) mentioned above, nuclear reaction yields, saturation factor, isotope abundance and relative atomic mass can be cancelled out. Using Equation (9), abundance ratios of the sample \((w_b/w_a)\) and the comparative standard \((K)\) are left.

\[
R^* = K \frac{w_b}{w_a} \quad (9)
\]

Therefore, the abundance of element \(a\) \((w_a)\) can be calculated by Equation (10):

\[
w_a = Kw_b \left( \frac{R^*}{R} \right) \quad (10)
\]

When the ratio is obtained as the \(\gamma\)-ray peak area ratio, Equation (11) can be used.

\[
\frac{R^*}{R} = \left( \frac{C_a^+ \phi(\gamma_a) \varepsilon(\gamma_a) \Omega^+}{C_b^+ \phi(\gamma_b) \varepsilon(\gamma_b) \Omega^+} \right) \left( \frac{C_a^- \phi(\gamma_a) \varepsilon(\gamma_a) \Omega^-}{C_b^- \phi(\gamma_b) \varepsilon(\gamma_b) \Omega^-} \right) \quad (11)
\]

where \(\phi(\gamma)\) is the branching ratio of the \(\gamma\)-ray, \(\varepsilon(\gamma)\) is the detector efficiency at the \(\gamma\)-ray energy, \(\Omega\) is the solid angle of the measurement, and \(C\) is the peak area. The asterisk designates the standard. Finally, all these factors can be cancelled out by applying the double ratio. The double ratio can be expressed as two \(\gamma\)-ray peak area ratios.

In this method, it is only necessary to know the abundance ratio \((K)\) of the comparative standard and amount of internal standard element \((w_b)\) added to the sample, respectively. It is not necessary to weigh the sample and the comparative standard irradiated, to monitor the photon flux on sample and standard by the flux monitors, or to adjust strictly the geometrical condition of measurement, because this formula only needs the activity ratio. However, the latter statement is valid in limits only since the functions of counting efficiencies of the analytical signal and the internal monitor signal over the distance of the sample from the detector might differ. This difference can be significant particularly in the close vicinity of the detector.

It is essential that the irradiation energy for both the sample and the standard is the same. The difference of matrix effect between the sample and the comparative standard cannot be compensated by this method.

As to the comparison of the internal standard method with the single comparator method\(^{38}\) as frequently utilized in NAA: in the single comparator method, the same amount of an element \((a)\) to be determined and the comparator element \((b)\) are irradiated and the activity ratio of element \(a\) to \(b\) is measured in advance. The activity ratio \((C)\), which is regarded as constant, can be expressed as shown in Equation (12).

\[
C = \frac{(\theta_a/AW_a) \sigma_a [1 - \exp(-\lambda_a t_a)]}{(\theta_b/AW_b) \sigma_b [1 - \exp(-\lambda_b t_b)]} \quad (12)
\]

To determine an element in the sample, a sample and single comparator pair is irradiated simultaneously and the abundance of the element \((w_a)\) can be calculated by the activity ratio \((A_a/A_b)\), the amount of comparator \((w_b)\) and constant as in Equation (13):

\[
w_a = Cw_b \left( \frac{A_a}{A_b} \right) \quad (13)
\]
Although the quantitative equation of the internal standard method is analogous to that of the single comparator method, the principles of both methods are quite different from each other. The accuracy of the single comparator method is mostly unsatisfactory in PAA, because it is very difficult to keep the activity ratio constant. The energy spectrum for every irradiation and the beam current during one irradiation cannot be considered constant for every accelerator.

For highly pure materials, one of the main matrix components can be used conveniently as an internal standard without adding an exotic element. This method was applied for the analysis of impurity or minor constituent in metals or alloys by Kato et al.\(^{35,37}\) If a matrix element (atomic number \(Z\)) leads to isotopes of \((Z - 1)\) or \((Z - 2)\) by the \((\gamma,\text{xn})\) or \((\gamma,\alpha,\text{xn})\) reactions, these radioisotopes can be used for internal standardization. Then, a \((\gamma,\text{xn})\) product from neighboring elements (atomic number \(Z - 1\) or \(Z - 2\)) can be chemically separated together with isotopes of \((Z - 1)\) or \((Z - 2)\) induced from the matrix. As these internal standards chemically behave like the \((\gamma,\text{xn})\) products from impurity, their activity ratio is always constant. Therefore, the unknown amount can be determined without correction of chemical yield.

When the internal standard is added to the sample, the following conditions are required: none or a negligibly small amount of internal standard exists in the sample; only one or two \(\gamma\)-rays emit from the internal standard; and \(\gamma\)-rays from the internal standard do not interfere with \(\gamma\)-rays to be analyzed. Sc, Y and Sm have been used routinely as internal standards for a variety of samples by Segebade et al.\(^{39}\) and Ce was used for the trace element analysis of aluminum alloys by Yagi and Masumoto.\(^{36}\)

To maintain maximum accuracy it is desirable that the half-life and \(\gamma\)-ray energy of the internal standard are similar to those of radioisotopes to be analyzed, and that the cross-section of the photonuclear reaction of the internal standard is similar to that of an element to be determined because the full energy spectrum of bremsstrahlung cannot be accurately monitored by using only one photonuclear reaction and also the photon flux tends to fluctuate in each irradiation.

**6.2 Internal Standard Method Coupled with the Standard Addition Method**

To achieve higher analytical accuracy without using any comparative standard and to compensate matrix effects arising from irradiation and measurement, the internal standard method coupled with the standard addition method has been proposed. This method was initiated by Lariaert et al.\(^{40}\) in NAA as the internal standard method. After Lariaert et al. applied it to NAA of minor elements in high alloy steels,\(^{41}\) Yagi and Masumoto\(^{42}\) revived it by the full use of high-resolution \(\gamma\)-ray spectrometry and a new sample preparation technique. In order to distinguish it from the method dealt with in the previous section, this method is called the internal standard method coupled with the standard addition method. In this section, the definition and characteristics of this method are described in some detail.

In this method, duplicate samples are taken. The accurate amount \((w_0)\) of element to be determined is added to one portion of sample. The sample and the standard addition sample are irradiated simultaneously and the activity ratios of the pertinent element and internal standard are measured for both sample \((R)\) and standard addition sample \((R')\).

The activity ratio of the standard addition sample can be expressed by Equation (14):

\[
R' = \frac{A_w^*}{A_b^*} = \frac{[(w_a + w_0)N_0\beta_a/AW_b]Q[1 - \exp(-\lambda_a t_0)]}{(w_bN_0\beta_b/AW_b)Q[1 - \exp(-\lambda_b t_0)]}
\]

Then, by calculating the double ratio \((R'/R)\), the amount of internal standard element \((w_b)\) is also cancelled out. As shown in Equation (15), a very simple relation is obtained.

\[
\frac{R'}{R} = \frac{w_a + w_0}{w_a}
\]

The unknown amount of \(w_a\) is calculated using Equation (16):

\[
w_a = \frac{w_0}{[(R'/R) - 1]}
\]

In this method, it is not necessary to know the amount of internal standard present in the sample \((w_b)\). Only the amount of element added to the sample \((w_0)\) is used for calculation. If an appropriate internal standard does not exist in the sample, the same amount of external element is added to the sample and the standard addition sample.

This method was applied to multielement analyses and one or more elements were used simultaneously as internal standards. For PAA of biological, geological and environmental samples, Na, Mg, Ca, Ti and Fe, usually inherent in natural samples, are useful internal standards because the concentrations of these elements are relatively high and half-lives and \(\gamma\)-rays of reaction products are convenient for the measurement. This method has been applied to PAA and charged particle activation analysis (CPAA) of biological materials,\(^{42-44}\) sediment,\(^{45,46}\) soil,\(^{47,48}\) fly ash\(^{49}\) and alloys.\(^{50-52}\)

The use of two or more internal standards is effective to cross-check the analytical results.\(^{53}\) The homogeneity of elements and internal standards in the sample and the standard addition sample is always checked by comparing with the standard deviations of activity ratios \((R'\) and \(R)\).
If \( \sigma(R^*) \) is always larger than \( \sigma(R) \) of a certain element, only this element was not mixed homogeneously at the standard addition step. If \( \sigma(R) \) is always larger than \( \sigma(R^*) \) of a certain element, this element is not homogeneous in the sample itself.

This method combines the characteristics of the internal standard method and that of the standard addition method. In the standard addition technique, comparative standards are not necessary. This method can eliminate several systematic errors, which are involved in the comparative method, such as the matrix composition and geometrical conditions of irradiation and measurement, and the analysis of the \( \gamma \)-ray spectrum.

In order to check whether loss or contamination of an element is caused during sample preparation, another portion of sample is prepared in the same procedure as the standard addition sample without adding an element to be determined and the double ratio \((R^*/R)\) is also measured. When this ratio is \(<1\), the pertinent element might be lost during the standard addition procedure. When this ratio is \(>1\), contamination has to be considered. The analysis of CRM by this method is useful to check the degree of homogeneity of the sample. As this method is capable of self-checking it is very useful for the analysis of reference materials.

### 6.3 The Stable Isotope Dilution Method

Stable isotope dilution activation analysis utilizes isotope analysis. For example, Ce has two stable isotopes, \(^{140}\text{Ce} \) (88.48\%) and \(^{142}\text{Ce} \) (11.08\%), which can produce \(^{139}\text{Ce} \) and \(^{141}\text{Ce} \), respectively, by \((\gamma, n)\) reactions. When an enriched isotope \(^{142}\text{Ce} \) is added to the sample, the activity ratio of \(^{139}\text{Ce} \) and \(^{141}\text{Ce} \) changes. The degree of the activity ratio change is relative to the abundance of Ce in the sample and the added amount of \(^{142}\text{Ce} \). The conditions of this method are that the elements to be determined consist of at least two stable isotopes, and these two or more isotopes produce radioisotopes that can be detected separately by \( \gamma \)-ray spectrometry.

Stable isotope dilution activation analysis is performed using the following steps: the enriched isotope \( j \) is used as a spike, in which the isotopic abundances \((\theta_i)\) of \( i \) and \( j \) are known; the enriched isotope \((w_i)\) is added to the sample; and the sample and the spiked sample are irradiated simultaneously. The activity ratio induced by two stable isotopes \((i \text{ and } j)\) is measured for the sample \((R_x)\) and the spiked sample \((R_m)\) using Equations (17) and (18).

\[
R_x = \frac{A_{ix}}{A_{i}} = \frac{(w_i\theta_{ix}/AW_x)\sigma_i[1 - \exp(-\lambda_i t_i)]}{(w_i\theta_{ix}/AW_x)\sigma_i[1 - \exp(-\lambda_i t_i)]}
\]  

\[
R_m = \frac{A_{im}}{A_{i}} = \frac{(w_i\theta_{im}/AW_m)\sigma_i[1 - \exp(-\lambda_i t_i)]}{(w_i\theta_{im}/AW_m)\sigma_i[1 - \exp(-\lambda_i t_i)]}
\]  

where the subscripts \( x, s \) and \( m \) indicate the sample, an enriched isotope and the spiked sample, respectively, \( w_i \) is the weight of element in the sample, \( w_s \) is the spiked amount of the enriched isotope, \( AW \) is the relative atomic mass, \( R \) is the activity ratio (isotope \( i / \text{isotope } j \)), and \( \theta_i \) and \( \theta_j \) are the isotopic abundances of isotopes \( i \) and \( j \) respectively.

Again the ratio of these activity ratios is used as shown in Equation (19):

\[
\frac{R_m}{R_x} = \frac{(w_i\theta_{ix}/AW_x)\sigma_i}{(w_i\theta_{ix}/AW_x)\sigma_i} = \left( \frac{R_m}{R_x} \right) \frac{\sigma_i}{\sigma_j}
\]  

Then, the equation is slightly simplified to Equation (20):

\[
\frac{R_m}{R_x} = 1 + \left( \frac{w_s}{w_i} \right) \frac{\theta_{ix}}{\theta_{ix}} (\frac{AW_x}{AW_s})
\]  

From Equation (20), the unknown amount \((w_s)\) of element can be obtained using Equation (21):

\[
w_s = w_i \frac{AW_x}{AW_s} \left( \frac{\theta_{ix}}{\theta_{ix}} \frac{R_m}{R_x} - \frac{\sigma_i}{\sigma_j} \right)
\]

This equation was introduced by Masumoto and Yagi(54) in 1983.

When highly enriched isotopes can be used as spikes, the abundance ratio \((\theta_i/\theta_j)_(ix)/(\theta_i/\theta_j)_x\) becomes much smaller than the activity ratio \((R_m/R_x)\). Then, a simple equation can be obtained, as shown by Equation (22):

\[
w_s = w_i \frac{AW_x}{AW_s} \left( \frac{\theta_{ix}}{\theta_{ix}} \frac{1}{(R_c/R_m) - 1} \right)
\]

As the unknown amount of an element can be determined by the activity ratio of two radioisotopes, the stable isotope dilution method is regarded as another type of internal standard method. In order to reduce error, the ratio \((R_m/R_x)\) should preferably range from 0.3 to 0.7.(55)

In PAA, this technique was proposed for the determination of Ca, Zn and Ce.(56) Furthermore, it was applied to PAA(56) and CPAA(57) of Sr in biological materials. In the case of isotope dilution, it is not necessary to determine the chemical yield when the element to be determined is separated before or after irradiation. Hence, Sr was separated chemically before irradiation. Simultaneous determination of Ca, Rb, Sr and Ce was tried in PAA(58) in order to show the applicability of this technique in multielement analysis.
7 APPLICATION

7.1 Analysis of Light Elements

One of the important features of PAA is the analysis of light elements, such as C, N, O, and F. In the book by Engelmann et al., PAA techniques for light element analysis have been described in detail and compared with chemical methods and CPAA. The radioisotopes produced by light elements are positron emitters. In order to analyze such elements, chemical separation after irradiation is mostly necessary. Fedoroff et al. systematically studied the separation of radiocarbon in molten salts and expanded their studies to the simultaneous determination of C and N.

In this section, some analytical examples of carbon and fluorine are described.

7.1.1 Determination of Carbon

Yoshioka et al. determined the carbon impurity in copper and gallium arsenide. In PAA, trace amounts of carbon can be determined by detecting $^{12}\text{C}$ produced by $^{12}\text{C}(\gamma,\text{n})^{11}\text{C}$. As $^{11}\text{C}$ is a positron emitter with a half-life of 20.39 min, a rapid chemical separation of radioactive carbon is necessary after irradiation (yet faster separation schemes have to be applied for oxygen analyses via $^{15}\text{O}$; half-life $= 2$ min). Copper samples were oxidized with Sn as a flux material, and GaAs with $\text{Pb}_2\text{O}_4$. $^{11}\text{CO}_2$ produced in the combustion process was collected as $\text{Ba}^{13}\text{CO}_3$. The separation procedure was completed within one half-life of $^{11}\text{C}$ after irradiation. In the case of Cu and GaAs, the sensitivity is $0.02\,\mu\text{g}\,\text{g}^{-1}$ or $10^{15}$ atoms $\text{cm}^{-3}$, respectively.

Carbon impurity in a highly purified semiconductor has been usually analyzed with IR spectrophotometry. This method uses the relationship between the IR absorbance and the carbon concentration. The absorption of certain wavelengths of IR light is effected by the resonance with a vibration mode of a chemical bond between carbon and the substrate. A nuclear reaction, however, is not influenced by the chemical state of carbon. This fact suggests that the calibration factor between carbon concentration versus absorbance of IR, which had been used formerly, should be reconsidered.

7.1.2 Determination of Fluorine

The ion-selective electrode (ISE) is commonly used for determining fluorine in an aqueous solution. However, trace amounts of fluorine are difficult to detect by an ISE. In PAA, fluorine can be determined by the $^{18}\text{F}(\gamma,\text{n})^{18}\text{F}$ reaction. In the case of high-level sodium contents in the sample, e.g., geological material, the irradiation energy should be reduced to 20 MeV because of the interfering nuclear reaction $^{23}\text{Na}(\gamma,\text{n})^{19}\text{F}$. For the sensitive analysis of fluorine, pyrolysis and lanthanide precipitation of fluorine-18 after 20 MeV irradiation have been proposed. The detectable concentration level was $0.06\,\mu\text{g}\,\text{g}^{-1}$ and rocks containing less than $10\,\mu\text{g}\,\text{g}^{-1}$ of fluorine were analyzed.

7.2 Multielement Analysis of Biological Materials

PAA of biological materials was reviewed by Kuttemperoor and Sato. By the development of high-resolution Ge detectors, PAA has been widely recognized as an efficient multielement determination technique of several biological materials, as reported by Kato et al.

Biological samples, especially several organs of animals and blood, usually contain Na and P at high concentration levels. As the neutron activation cross-section of $^{23}\text{Na}(n,\gamma)^{24}\text{Na}$ is very large and the Compton scattering by $\gamma$-rays from $^{24}\text{Na}$ causes very high background in the $\gamma$-ray spectrum, $^{24}\text{Na}$ often masks other $\gamma$-rays emitted by minor and trace elements in NAA. Furthermore, since $^{32}\text{P}$ due to phosphorus produces high-energy $\beta$-ray emission followed by bremsstrahlung, detection of trace elements is frequently perturbed, especially in blood and bone samples.

In the case of PAA, high intensity radiation produced in biological samples is due to $^{11}\text{C}$, $^{13}\text{N}$ and $^{15}\text{O}$ induced by the $(\gamma,\text{n})$ reaction from carbon, nitrogen and oxygen, respectively. Fortunately, $\gamma$-ray measurement can be carried out after a comparatively short cooling period, say about 3 h after irradiation, as the longest half-life of the aforementioned nuclides is 20 min ($^{11}\text{C}$). Even after 3 h, several short- to medium-lived radioisotopes such as $^{20}\text{Al}$ from Si, $^{38}\text{K}$ from K, $^{43}\text{K}$ from Cl, $^{54}\text{Mn}$ from Fe and $^{87}\text{Sr}$ from Sr can often be measured. Moreover, the carbon reaction can be suppressed by activating at an energy below its $(\gamma,\text{n})$ threshold (about 20 MeV). Many elements which can hardly be determined by NAA, such as Mg, Ca, Ni, Zn, Sr, Zr, Mo, I and Pb, are easily analyzed by PAA. In 1984, PAA of Zr in biological samples was performed without chemical separation. The radioisotopes of medium half-life, such as $^{24}\text{Na}$ from Mg and $^{43}\text{K}$ and $^{47}\text{Ca}$ from Ca, sometimes show up as a source of undesired Compton background. To remove background activities, Yamashita and Suzuki proposed a group separation scheme using complex formation of metals with tropolone-5-sulfonic acid and collecting on anion-exchange resin.

7.3 Analysis of Geological and Environmental Materials

PAA has been applied for the analysis of geological and environmental materials. About 20 to 30 elements can be determined instrumentally and simultaneously. The list of determinable elements covers major to trace elements with chemical methods and CPAA. The radioisotopes produced by light elements are positron emitters. In order to analyze such elements, chemical separation after irradiation is mostly necessary. Fedoroff et al. systematically studied the separation of radiocarbon in molten salts and expanded their studies to the simultaneous determination of C and N.
elements, essential to toxic elements, transition metals, heavy metals, alkali and alkaline-earth metals, halogens and others. These elements are Na, Mg, Si, Cl, K, Ca, Sc, Ti, Cr, Mn, Fe, Co, Ni, Zn, As, Rb, Sr, Y, Zr, Nb, Mo, Sb, I, Cs, Ba, Ce, Ti, Pb and U. The pioneering work of multielement analysis of rock and soil was done by Kato et al.\(^\text{71,72}\) and Chattopadhyay and Jervis\(^\text{73}\) respectively. PAA of atmospheric matter was reported by Aras et al.\(^\text{74}\) and Kato et al.\(^\text{75}\)

Geological and environmental samples contain various elements with high neutron capture cross-section, such as Na, Sc, Mn, Co, Br and Eu. In NAA, these elements induce high intense radioactivity even at trace levels. In PAA, radioactivities induced by major elements such as Na, Mg, Ca, Ti, Mn and Fe are relatively low in most cases. As the \((\gamma,p)\) reactions are the most efficient reactions of Mg, Ca, Ti and Fe, the radioactivities induced by these elements can be reduced by lowering the irradiation energy well below 30 MeV.

Several selected elements advantageously detectable by PAA were also determined. Determination of Ni by a coincidence technique,\(^\text{76}\) determination of Nb and Y for the characterization of standard rocks,\(^\text{77}\) and determination of I, Ti and U in environmental materials\(^\text{78}\) are typical examples.

Deep-sea sediment\(^\text{79,80}\) and volcanic rocks\(^\text{81}\) were analysed by PAA to discuss the sedimentation process and the distribution of minor elements during the formation of rock, respectively.

### 7.4 Multielement Analysis of Raw Materials and Industrial Products

Gijbels and Hertogen\(^\text{82}\) reviwed PAA of ore and minerals. Albert\(^\text{83}\) discussed trace analysis using PAA in a review article of nuclear methods. As mentioned before, NAA of certain matrices is sometimes very difficult, because of the self-shielding problem and high radioactivity caused. Typical examples are rare-earth elements, cadmium and boron, which also have large neutron capture cross-sections, and uranium ore and phosphate, which lead to fission products. To verify the capability of PAA in these fields, lanthanides in boron carbide were determined instrumentally by PAA.\(^\text{84}\) Detection limits of these elements were found in the submicrogram range. Twenty-eight impurities in boron were also determined by PAA.\(^\text{85}\)

### 8 COMPARISON WITH OTHER ACTIVATION ANALYSIS METHODS

In this section, the different features, advantages and disadvantages of the three activation analysis techniques PAA, CPAA and NAA are compared regarding the irradiation technique, nuclear reactions induced as well as sensitivity and selectivity achievable. Only the basic methods are considered; special techniques like nuclide-induced photodisintegration or 14 MeV NAA are excluded from discussion.

#### 8.1 Irradiation

##### 8.1.1 Photon Activation Analysis

The energy distribution of bremsstrahlung is continuous from zero to the incident electron energy. As high-energy photons have a high penetration power for most materials, a stack of several samples can be irradiated simultaneously. The matrix effect normally is very small in PAA. The energy distribution is not changed drastically during penetration. As the photon flux is decreased exponentially by scattering and absorption in the matter, the photon flux density on each sample should be monitored. Although the incident electron beam is focused, bremsstrahlung cannot be focused. As already touched on, bremsstrahlung has a nonisotropic spatial distribution which depends on the converter thickness and the geometry of the electron beam.

##### 8.1.2 Charged Particle Activation Analysis

As the charged particles are strongly retarded in a sample by scattering, particles are stopped at a certain range. Both the induced radioactivity and the predominant reaction type induced change along with the depth since both flux and energy of the respective particle change. Therefore, range or stopping power of charged particles in each material should be taken into account for the quantitative analysis. It is difficult to irradiate a stack of samples. However, CPAA can efficiently be applied to analyze surface layers of materials. Hence, the surface contamination problem is more imminent than in NAA or PAA. Local heating of the materials by charged particle is a severe problem for the analysis of organic and other sensitive materials. Charged particles can be focused even on extremely small areas. Thus CPAA can be used favorably for the analysis of small spots, e.g. in the study of areal elemental distributions.

##### 8.1.3 Neutron Activation Analysis

Since the neutron has no electrical charge it can penetrate the bulk of samples more easily. The absorption cross-sections of neutrons are strongly dependent on the nuclear properties of each element. The energy distribution of reactor neutrons shows Maxwell–Boltzmann distribution according to the temperature in the reactor. In most cases, many samples can be irradiated simultaneously
and homogeneously in a capsule. The self-shielding effect of certain elements, such as Cd, should be considered because the neutron flux is locally depressed in the presence of these elements. Neutron beams cannot be focused except, to a certain limited extent, with a neutron beam tube installed at the reactor.

8.2 Comparison of Nuclear Reactions Induced

8.2.1 Photon Activation Analysis

As mentioned above, photonuclear reactions are mainly controlled by the photoabsorption process (giant resonance, see above) giving rise to the \((\gamma,n)\)-type reaction. The resonance energy ranges from about 10 MeV for heavy elements to about 20 MeV for light elements. The yield of the photoneutron reaction increases with atomic number. For analysis, \((\gamma,n)\) and \((\gamma,p)\) reactions are utilized normally. Higher-order reactions such as \((\gamma,2n)\), \((\gamma,3n)\) or \((\gamma,\gamma')\) mostly appear as sources of interference. In practice, 30 MeV bremsstrahlung has proven to be optimal in most applications.

8.2.2 Charged Particle Activation Analysis

In CPAA, protons, deuterons, \(a\) and \(^{3}\text{He}\) particles are commonly used as probes. In the case of charged particle activation, the Coulomb barrier effect should be considered. For heavier elements, higher excitation energies are needed to penetrate the coulomb barrier and to induce nuclear reactions. As several reaction types can be induced at this excitation energy many different radioisotopes are observed and the probability of nuclear interference is considerable. Since the higher atomic number elements are more likely to be subject to nuclear interference than light ones, CPAA is not normally suitable for the analysis of heavy elements.

In the case of deuteron and \(^{3}\text{He}\) activation, many nuclear reactions are exothermic and can be induced at low excitation energy. Such nuclear reactions have been applied to the analysis of light elements. The irradiation particle and irradiation energy can be selected quasi-freely for the selective analysis of certain elements.

8.2.3 Neutron Activation Analysis

In NAA, thermal and epithermal neutrons are used. Neutrons are absorbed by elements according to the \(1/v\) law and by resonance reactions. The thermal neutron capture cross-section is inversely proportional to the velocity of the neutron, and this is known as “the \(1/v\) law”. The resonance reactions induced in the epithermal region are often used for the analysis of specific elements using cadmium shielding of the sample because cadmium has very high absorption cross-section for thermal neutrons. The analysis of light element is very difficult. Unlike in PAA, there is no regularity in the neutron absorption reactions. Nonetheless, NAA can be used for multielement analysis of a large variety of materials.

8.3 Sensitivity and Selectivity of Elements to be Determined and Applicability to Various Kinds of Materials

8.3.1 Photon Activation Analysis

PAA is used for the analysis of light elements such as C, N, O and F, medium elements such as Ti, Ni, Sr, Zr, Nb, and Y, and heavy elements such as Pb, which are very difficult to analyze by NAA. Furthermore, PAA is suitable for the analysis of matrices which contain some elements of high neutron capture cross-section, e.g. boron and noble metals. As photonuclear reaction cross-sections systematically increase with atomic number, PAA can be applied to the analysis of heavier elements in light matrices, such as natural materials (rocks, soils, dusts, organics, etc.). The sensitivity for trace analyses is mostly sufficient (microgram per gram region and below), although not as good as in NAA for the average case. Using appropriate equipment and with the exception of a few interference cases (see above), PAA is highly selective due to discrete energy signals of the respective activation products.

8.3.2 Charged Particle Activation Analysis

CPAA is advantageous particularly for light element analysis. CPAA has often been applied to the impurity analysis of industrial materials. The shape of the sample is critical, so the application is somewhat restricted. The average sensitivity is comparable to that of PAA whilst the selectivity is frequently limited due to numerous nuclear reactions eventually induced in the individual element.

8.3.3 Neutron Activation Analysis

NAA can detect many elements instrumentally, except for light elements. Extremely low detection limits are achievable for a good number of elements, e.g. several rare earth elements, noble metals and others; the respective detection limits are lower partly by orders of magnitude, as compared with PAA and CPAA. Thus, NAA is suitable for sensitive analysis of trace elements in various types of materials. However, interference through eventual excessive matrix activities have to be taken into account. Moreover, in the normal case, only small sample masses should be irradiated because of the intense radioactivity induced. Thus, problems of representativeness might arise. As to the selectivity, see section 8.3.1.
9 CONCLUSION

PAA offers sufficient sensitivity for the analysis of a great number of elements covering the entire periodic table. A large variety of sample types can be analyzed. The quality of PAA results can be improved by application of quantitative methods, such as the internal standard method or the stable isotope dilution method. In the case of the classical comparative method, the use of synthetic multielement standards of acrylamide or silica matrix yields significant improvement of accuracy.

In PAA (also in NAA), samples can be measured repeatedly. A laboratory automation system using a small robot for sample changing has released analysts from the tedious work of sample handling and data acquisition during γ-ray measurement. Moreover, many “human” sources of error can be avoided. Such systems also assist researchers of many other fields using activation analysis and other radioactivity measurements.

Although other, nonactive analytical methods underwent dramatic improvement in recent years concerning sensitivity and other features, PAA and other activation techniques can offer specific advantages, e.g. the analysis of elements difficult to analyse by other methods. Moreover, purely instrumental and even nondestructive analyses are state-of-the-art in PAA.

Thus, as trace characterization is still important in material science, environmental science and other fields, PAA can contribute to the analysis of light to heavy elements.

Particle-induced X-ray emission (PIXE) is the most popular among the ion beam analysis (IBA) techniques, which are based on the use of the specimen to be analyzed as a target for a beam of accelerated particles. The detection of the radiation induced by the beam bombardment is then used to discriminate and quantify the presence of the different elements in the specimen. In PIXE, what is exploited is in particular the X-rays emitted from the target, whose energies are characteristic of the emitting atomic species. After a general, simple description of the main features of PIXE, with a short historical overview and a brief comparison to other X-ray fluorescence (XRF) techniques, the article covers in greater depth all the specific aspects of this “nuclear” technique. The basic aspects of X-ray emission from the atoms are first recalled; then, the extraction of quantitative compositional data from thin and thick specimens is explained, and a discussion is given of the excellent performance of PIXE in terms of minimum detection limits (MDLs), and of the factors affecting them. A technical description then follows of how proper beams for PIXE are produced and of the experimental set-ups commonly used, with particular emphasis on the external-beam arrangements. The X-ray detector characteristics, the electronics for constructing the energy spectra, and the software processes for their deconvolution, leading to the extraction of quantitative data, are then briefly described. The last section surveys the main analytical applications of PIXE in various fields (environmental monitoring, biomedicine, earth sciences, cultural heritage), with no intent of exhaustiveness but rather with the purpose of focusing on when and why PIXE may be particularly suitable in each of them.

1 INTRODUCTION

1.1 General Features

PIXE is a technique for the elemental analysis of a sample. This is used as a target for the bombardment with a beam of accelerated particles; the interactions of the beam particles with the target atoms lead to the emission of X-rays of characteristic energies, through the detection of which the target composition can be deduced. The PIXE technique is often also referred to as proton-induced X-ray emission, owing to the fact that in this technique protons are almost universally chosen to induce X-ray emission. For this reason, the following discussion always considers the case of protons; no difference of either theoretical or practical relevance occurs anyway with beams of other particles. The PIXE technique belongs to the category of IBA techniques, and is perhaps the most widely used among them.

The method makes it possible to detect simultaneously and with great sensitivity almost the full range of elements present in the analyzed sample. In practice, some limitations partially restrict the number of detectable elements, but the multi-element capability is actually retained to a very large extent. As a rule of thumb (to be better specified below), one might state that in a single measurement – typically lasting few minutes – all elements with $Z > 10$ are detected with MDLs down to trace levels.
The working principle of PIXE is quite simple. Using a small (usually electrostatic) accelerator, a beam of particles is produced with an energy of typically 2–3 MeV. The beam particles, when impinging on a target, interact with atoms and nuclei of the target itself: in particular, the inner shells of the target atoms may be ionized. The inner shell vacancy is promptly filled (within a time interval of the order of $10^{-15}$ s) by an outer electron, and the difference $\Delta E = E_o - E_i$ of the electron binding energies $E_o$ and $E_i$ in the outer and inner shell is released. One of the processes through which the energy $\Delta E$ can be released is just the emission of an X-ray of that energy. A competing mechanism (the Auger effect) is the energy transfer to another electron of an outer shell, which is consequently ejected with a kinetic energy $E_k = \Delta E - E_i$, where $E_i$ is the binding energy of the electron to which $\Delta E$ is transferred. Figure 1 shows schematically the processes of X-ray and Auger electron emission.

The energy of the emitted X-ray (or Auger electron) is clearly characteristic of the emitting atomic species, being the difference of electron binding energies that are indeed characteristic of the atomic species. Thus, the energy spectroscopy of the X-rays from the sample during particle beam bombardment provides an analysis of its composition. Such an analysis is **multi-elemental**, because all the atomic species present in the target undergo interactions with the beam particles, and therefore emit characteristic X-rays. It is also **quantitative**, because during an irradiation the number of interactions of the beam particles with the atoms of a given species is obviously proportional to the abundance of atoms of that species in the target. Under most circumstances (better specified in the following) the analysis is also **nondestructive**, because the beam particle–target atom interactions do not produce significant alterations in the target and involve only a tiny fraction of the target atoms. In any case, the possibility of further analysis (by the same or different techniques) is guaranteed for the same specimen.

The principle of operation of PIXE is the same as that exploited to perform elemental analysis through electron probe microanalysis (EPMA) or XRF, but with a different ionizing agent (protons rather than electrons or primary electromagnetic radiation, respectively). This difference has consequences in terms of important analytical parameters such as MDLs, range of detected elements, or sample depth probed (as briefly discussed later).

The possibility of performing PIXE while keeping the sample in the atmosphere (**nonvacuum** or **external PIXE**), and that of miniaturizing the beam size down to 1 µm or even less (**micro-PIXE**), make it a very versatile technique. All kinds of samples may be quantitatively analyzed: solid, gaseous, or liquid (the latter two with an external beam). Elemental mapping may also be performed by scanning the beam on the sample during analysis (or moving the sample under the beam).

In PIXE, the detection and discrimination of X-rays emitted under beam bombardment is usually performed through the use of solid state Si(Li) detectors (or, much less frequently, hyperpure Ge detectors), which discriminate the different X-rays by their different energies. The detector response signals are proportional to the energy releases within the active volume of the detector; this way of discriminating different X-rays is therefore called energy-dispersive spectroscopy (EDS). The energy resolution is generally adequate for unambiguous discrimination. Conventionally, resolution is given as the full width at half-maximum (fwhm) of the peak corresponding to the 5.9-keV X-ray from Mn. A typical value is around 160 eV, but even better resolution may be reached, especially for small-surface detectors and when a long time constant is used for the linear shaping of the detector signals. To give an idea of the kind of information collected, Figure 2 shows two typical X-ray spectra obtained with Si(Li) detectors in a PIXE measurement of a sample of aerosol. We return later to a discussion of the characteristics of the spectra (in particular the background shape) and to the way of treating partially overlapping lines. Here the intention is to point out that the multi-element analytical capability is a real feature of PIXE with EDS, and not just a theoretical claim.
Figure 2 PIKE spectra from a sample of aerosol collected on a Millipore® filter. The spectra refer to the same sample, but have been recorded simultaneously by two Si(Li) detectors in different geometries (see Figure 11, and the discussion of two-detector set-ups in section 2.6.3). The spectrum acquisition time was about 7 min, at a proton beam current of 5 nA.

By using Bragg spectrometers that exploit X-ray diffraction from a crystal, wavelength-dispersive spectroscopy (WDS) may also be performed, which allows a much better energy resolution (by a factor of 50 or so). The WDS technique is clearly at a premium to solve close multiplets of X-rays of similar energies from different elements, but a serious drawback is a drastic drop of detection efficiency. In typical PIXE set-ups for analytical purposes, WDS is therefore never accomplished, because one of the great analytical pros of the technique, i.e. its high sensitivity, would be lost. After all, even with EDS most ambiguities may be solved by using other X-rays from the same element as markers of its presence. Thus, the use of WDS is left in general to studies of basic atomic physics, such as changes of electron binding energies as a function of chemical state, rather than to analytical applications. For this reason, we will not discuss WDS any further in this context.

1.2 Brief Historical Overview and Review Literature

The PIXE technique was established as a universal analytical technique by Johansson et al. in the early 1970s. Its popularity and the range of applications have constantly increased over the years. Today (1999), tens of laboratories throughout the world currently use PIXE for elemental analysis in fields as diverse as environmental pollution, biology and medicine, earth sciences, material sciences, art and archaeology, historical document examination, and forensic science. Comprehensive descriptions of the theoretical basis of the technique and its practical use in the main fields of application are available. Dedicated conferences on “Particle-induced X-ray Emission and its Analytical Applications” have been held every third year since 1977; PIXE sections have been and are present in many other, more general, series conferences (e.g. International Conference on Ion Beam Analysis, European Conference on Accelerators Applied to Research and Technology, and others). Specific conferences on nuclear microprobes (where micro-PIXE applications are widely represented), and more recently on the applications in the field of biomedicine (bio-PIXE Symposia), are also periodically held.

The literature on PIXE work is distributed over several journals dealing with the fields of the specific applications. However, the above-mentioned Proceedings of the International PIXE Conferences – published by North Holland as separate issues of the review Nuclear Instruments & Methods in Physics Research, Section B – are a good source of concentrated information concerning both applications and basic physical and technological advancements. The journal International Journal of PIXE (published by World Scientific Publishing Co Pte Ltd, Singapore) contains topical and review articles on the various fields of application.

1.3 Comparison with other X-ray-based Analytical Techniques

1.3.1 Electron Probe Microanalysis

1.3.1.1 Minimum Detection Limits

The absence of a primary bremsstrahlung (BS) continuum in the PIXE spectra (section 2.3.1), with the consequent low background in the energy spectra, is the main reason for much better (i.e. lower) detection limits in PIXE with respect to EPMA. In the latter, primary BS gives rise to a considerable, continuous background that extends to 20–30 keV (20–30 kV being the typical accelerating voltage used in the electron gun). This background is therefore present over all the energy region of interest for elemental analysis by X-ray line spectra. As X-ray production cross-sections for EPMA and PIXE are comparable under optimum conditions, the much lower backgrounds in PIXE spectra translate into better MDLs, typically lower by more than two orders of magnitude in PIXE with respect to EPMA.

1.3.1.2 Probed Depth

The range of electrons typically used in EPMA ($E_e = 20–30$ keV) is of the order
of a few micrometers at most, in light-\(Z\) matrices. This is consequently also the investigated depth from surface with EPMA, for all elements. As discussed below, in typical PIXE \((E_p = 2 – 3 \text{ MeV})\), the range traversed by protons is about 10 times larger; for higher-\(Z\) elements (detected through higher-energy X-rays) the probed depth is consequently much larger in PIXE than for EPMA. For the detection of lighter elements the effects of X-ray self-absorption (section 2.2) become dominant after only a few micrometers and the difference in the probed depth between the two techniques becomes smaller.

### 1.3.2.1 Minimum Detection Limits
Both PIXE and XRF can be used for trace-element analysis down to parts per million (ppm) levels. The difference between the two is the behavior of the sensitivity curve with \(Z\). Generally speaking, due to the different ionization mechanisms (and the consequent trends of X-ray production cross-sections) XRF has lower MDLs for higher-\(Z\) elements than PIXE, whereas the analytical capability of PIXE extends to lower-\(Z\) elements. However, for both techniques the sensitivity curve can be varied by changing the energy of the ionizing agent (primary electromagnetic radiation and protons, respectively). The XRF method may become totally blind to higher-\(Z\) elements when choosing an exciting radiation suitable for obtaining lower MDLs for lower-\(Z\) elements, and vice-versa, whereas PIXE preserves the total range of detected elements even when optimized (by varying the proton energy) with a better sensitivity to lighter or heavier elements.

### 1.3.2.2 Probed Depth
XRF probes considerably greater depths than standard energy PIXE as far as the heavier elements are concerned. For the lighter-\(Z\) elements (under conditions when XRF can detect them) it is again the self-absorption of low-energy X-rays – rather than the excitation mechanism – that determines the effective probed depth. Thus the difference is smaller.

### 1.3.2.3 Lateral Resolution
The possibility of obtaining real microbeams for PIXE has been mentioned in section 1.3.1. As far as XRF is concerned, until recently the typical spot over which XRF analysis was carried was of the order of square centimeters. The analysis of much smaller spots required strong collimation, and this drastically decreased the exciting radiation intensity and therefore made measurement times unduly long. However, the recent development of focusing techniques for X-radiation (based on capillary light-guides suitable in the range of X-ray wavelengths) has opened up new possibilities of miniaturizing the exciting X-ray beams for XRF, while still preserving acceptable intensities. The useful spot size obtained with these techniques is now of the order of some tenths of a square millimeter.

### 1.3.2.4 Nonvacuum Analysis
As with PIXE, XRF can be easily accomplished in nonvacuum conditions (although commercial XRF equipment is usually designed for in-vacuum analysis). In this respect there is no technical difference between the two techniques.

### 1.3.2.5 Nonlaboratory Analysis
Portable XRF equipment has been developed, mostly based on the use of an X-ray tube as the source of electromagnetic exciting radiation. Although some limitations exist when performing fully quantitative analyses – especially for light elements – the opportunity to perform in situ analyses on non-transportable materials is considerable. The need for a particle accelerator to produce the beam that excites X-ray emission makes conventional PIXE an intrinsically nonportable technique. However, in the late 1990s portable PIXE equipment, based on the use of a purely \(\alpha\)-emitting source \(^{210}\text{Po}\), has been developed and tested with success.\(^{3,4}\) The present limitation of this apparatus is the low intensity of the \(\alpha\)-beam due to isotropic emission of the particles from the source. This makes the measurements much more time-consuming than in the laboratory. Further developments in the relative source–sample–detector geometry are underway to improve the performance of this interesting variant to standard PIXE.
2 IN-DEPTH REVIEW OF THE TECHNIQUE

2.1 Basic Aspects of X-ray Emission from Atomic Shells

Let us first recall the spectroscopic nomenclature for atomic shells and for X-rays corresponding to electron transitions between them.

The potential energy is set to zero for free electrons, whereas electrons in the atomic shells have increasingly negative energies the more bound they are. The innermost electronic shell (principal quantum number \( n = 1 \)) is the K shell, and corresponds to the most tightly bound electrons; therefore, for any given element, K electrons have the minimum energy value. Examples of K-level energies are \(-1072\) eV for Na, \(-4038\) eV for Ca, \(-7113\) eV for Fe, \(-11\) 103 eV for Ge, \(-25\) 514 eV for Ag, \(-37\) 441 eV for Ba, and \(-88\) 005 eV for Pb.

The second shell (principal quantum number \( n = 2 \)) is the L shell, with subshells L₁, L₂ and L₃ corresponding to \((l = 0, j = 1/2), (l = 1, j = 1/2), (l = 1, j = 3/2)\), respectively. Examples of level L₁, L₂, and L₃ energies are: \(-63.3\), \(-31.1\), and \(-31.0\) eV for Na; \(-438\), \(-350\), and \(-346\) eV for Ca; \(-846\), \(-721\), and \(-708\) eV for Fe; \(-1414\), \(-1248\), and \(-1217\) eV for Ge; \(-3806\), \(-3524\), and \(-3351\) eV for Ag; \(-5988\), \(-5624\), and \(-5247\) eV for Ba; and \(-15\) 860, \(-15\) 200, and \(-13\) 035 eV for Pb.

The sequence of other shells is then M, N, and O, with principal quantum numbers \( n = 3, 4, \) and 5, respectively, with less tightly bound electrons (this applies to higher-Z elements having a large number of electrons).

Once a vacancy is created in an inner shell (by any ionizing agent), not all electronic transitions from outer shells or subshells are possible. Transition selection rules arise from quantum mechanical laws, so that only certain transitions are permitted, each having a well defined probability.

In the case of ionization from the L or superior shells, the Coster–Kronig effect must be taken into account. For the L shell, this consists of a nonradiative transfer of a vacancy, primarily created in the L₁ or L₂ subshell, to a higher L subshell (L₂ or L₃ for primary L₁ ionization, L₃ for primary L₂ ionization). Coster–Kronig transitions occur before the filling from an outer electron takes place; the electron transition energy is then varied. The probabilities of L₁ to L₂ (\( f_{12} \)), L₁ to L₃ (\( f_{13} \)) and L₂ to L₃ (\( f_{23} \)) Coster–Kronig transitions are high (up to over 50% for the L₁ to L₃ transition), and vary with atomic number. Similar and even more complicated effects take place when the primary ionization occurs in a shell higher than L. Although the Coster–Kronig effect is important from the point of view of basic atomic physics, it has no practical consequence for quantitative analyses based on induced X-ray classification, such as PIXE, EPMA, and XRF. In fact, it can be treated as an effective change of ionization probability of the various subshells and automatically taken into account when performing quantitative PIXE measurements, for which the knowledge of ionization cross-sections is essential (section 2.2).

Once an ionization has been produced in an inner shell, deexcitation of the atom can be accomplished by X-ray or Auger electron emission. The ratio of the number of X-ray emissions to the total number of ionizations produced in the given shell is called the fluorescence yield relative to that shell and is usually indicated with \( w \) (\( w_K, w_L, \) etc.). For the L and higher shells, subshell ionizations and consequently subshell fluorescence yields can be considered separately.

Fluorescence yields may be calculated theoretically and measured experimentally.⁵⁻⁸ They are a function of the atomic number \( Z \) and Figure 3 shows the behavior of \( w_K \) and \( w_L \) versus \( Z \).

The nomenclature for X-rays emitted as a consequence of an outer-electron transition following inner-shell ionizations recalls both the primary vacancy location and the filling electron provenance. These are referred to as K-series, L-series, M-series, etc. X-rays, depending on the initially ionized shell. Within each series, the further specification is then related to the provenance shell of the electron. \( K_a \) and \( K_b \) X-rays correspond to the filling electron coming from the L and superior shells, respectively, with still further distinctions (\( K_{a1}, K_{a2}, K_{b1}, K_{b2}, K_{b3} \)) depending on the provenance subshells. Figure 4 gives a summary of the X-ray nomenclature for the main lines of the K and L series.

Because electron binding energies increase with \( Z \), X-ray energies also increase with the atomic number. Figure 5 shows the trend for X-ray energies of the K and L main lines as a function of \( Z \).

Within each X-ray series, the intensity ratio of the different transitions varies with \( Z \).
2.2.1 Thin Specimens

The proton interactions with the inner shell electrons of the target atoms produce ionizations. The number of ionizations $N_{\text{ion},j}(Z)$ produced in a given shell $j$ ($j = K, L, M, \ldots$) for a given atomic species $Z$ in the target is obviously proportional to the target concentration of that atomic species, to the number of particles $N_p$ having passed through the target and to the thickness $t$ of the sample (Equation 1): \[ N_{\text{ion},j}(Z) = \sigma_{\text{ion},j} N_Z t N_p \] where $N_Z$ is the number of atoms of atomic number $Z$ per unit volume. The term $\sigma_{\text{ion},j}$ is the ionization cross-section for the given shell $j$. As seen from Equation (1), it has the physical dimensions of an area, and is clearly a measure of the probability of the interaction giving rise to the specific ionization. Except for the case of the K shell, ionization cross-sections are made up of more terms, corresponding to ionizations of the various subshells, for instance $\sigma_{L_\alpha}, \sigma_{L_\beta},$ and $\sigma_{L_\gamma}$.

Measured values of K- and L- ionization cross-sections have been reported in a large number of papers; a much smaller amount of data is available for the M-shell case.

For the K shell, a collection of measured values is available\(^9\) and a set of reference values based on statistical analysis of a compendium of published data has been compiled.\(^10\) With the exception of very low atomic numbers, the results of the so-called ECPSSR (see below for a justification of the acronym) theory of the particle–electron interaction\(^11,12\) agree within about 3%\(^13\) with the best experimental data. This theory (developed from the pioneering work of Brandt and Lapicki\(^14,15\)) treats the deflection and velocity change of the particles due to the Coulomb (C) field, the perturbation of the atomic stationary state (PSS) by the projectile, relativistic effects (R), and energy loss (E) during the collisions between beam particles and atomic electrons. For each element, the cross-section data (reference or theoretical) may be fitted as a function of proton energy $E_p$ with a fifth-order logarithmic polynomial.\(^16,17\) A universal treatment over a wide range of elements and proton energies with just six fitted parameters altogether, yielded – in the early stages of development of PIXE – a reasonable although not completely satisfactory reproduction of the tabulated data. However, using a distinct set of polynomial coefficients for each atomic number, tabulations can be reproduced within 1%.

An operational definition of “thin” and “thick” for a PIXE measurement is given below; for the moment, when referring to a thin specimen let us think of a few atomic layers.

2.2 Quantitative PIXE Analysis

Although a unified mathematical treatment of the procedure for a quantitative PIXE analysis might be given for all kinds of samples, it is easier to understand the principle by first examining the case of thin samples.

![Diagram of X-ray transitions](image)

**Figure 4** Summary of the main X-ray transitions to the K and L levels and of the corresponding nomenclature. (Reproduced by permission from Johansson et al.\(^11\))

![Energy plot](image)

**Figure 5** Energies of the main K- and L-series X-rays as a function of the element \(Z\). (Reproduced by permission from Johansson et al.\(^11\))

The ratio $I(K_\beta)/I(K_\alpha)$ of the two main groups ($\beta$ and $\alpha$) for K-series X-rays increases rapidly from 1.3% for Al (the lowest-$Z$ element where $K_\beta$ rays are possible) to 12% for K, then much more slowly (14% for Zn, 19% for Zr, 22% for Sn, etc.). The ratio $I(L_\beta)/I(L_\alpha)$ of the two main groups of the L-series X-rays decreases from about 70% in Sn to about 55% in the highest-$Z$ elements; contrary to the K-series case, the $I(L_\beta)/I(L_\alpha)$ ratio also displays a dependence on the ionizing particle energy, but this effect is not very pronounced and is always known with sufficient accuracy for the purpose of spectra deconvolution.
The situation is more complex for the L shell, in which the ionization cross-sections differ and have a different dependence on the proton energy for the three subshells. As a consequence, the relative intensities between the various L lines also have a dependence on proton energy, which is not the case for K lines. Coster–Kronig transitions further complicate the overall picture; thus, comparison between experimental values (extracted for instance from the compilation of L X-ray production cross-sections in Cohen[18]) and theoretical predictions (such as the ECPSSR approach[19]) is more difficult and the agreement less satisfactory.

The trend of $\sigma_{ion,K}$ and $\sigma_{ion,L}$ with proton bombardment energy, taken from ECPSSR calculations for some elements, is shown in Figure 6. A strong decrease with increasing $Z$ is apparent, especially for the K-shell ionization cross-sections. A strongly increasing trend with increasing $E_p$ occurs within the range of proton bombarding energies usually adopted. The cross-section reaches a maximum when the projectile velocity matches that of the ejected electron. Further increase of projectile energy results in a slow decrease in cross-section. It is apparent from Figure 6 that the increase with $E_p$ is larger for higher values of $Z$ so that, in general, working at higher energies makes the analysis of heavier elements comparatively more sensitive.

For the M shell, much less systematic work has been done. However, although little use is normally made in PIXE of the detected M-series X-rays for the quantification of the high-Z elements, knowledge of M-subshell ionization cross-sections, and consequently of the intensity ratios of M lines, would be important.

Indeed, in X-ray spectra from complex samples, the M lines from high-Z elements overlap the K or L lines of lighter elements so that a safe deconvolution of the multiplets must rely also on (experimental or theoretical) knowledge of the intensity ratios of the various M lines.

The product of ionization cross-section and fluorescence yield for a given shell gives the cross-section $\sigma_X$ for the production of an X-ray of the corresponding series; from what has been said it follows that $\sigma_X$ is also a function of $Z$ and $E_p$. As stated above, within each series the branching ratio among the different lines is a slowly varying function of $Z$ and, for the L shell, this also depends a little on the particle bombarding energy.

In terms of X-rays produced, the equivalent of Equation (1) is given by Equation (2):

$$N_X(Z) = \sigma_X N_{Zt} N_p$$

The angular distribution in the emission of the produced X-rays is isotropic with respect to the beam incidence.

Equation (2) can be rewritten in terms of areal density $\rho Z t$ of the element $Z$ (mass per unit area normal to the beam, with $\rho$ standard volumic mass density) as:

$$N_X(Z) = \sigma_X N_{Av} \rho Z t \frac{Q}{A e}$$

where $N_{Av}$ is Avogadro’s number and $A$ the atomic mass of the species. In Equation (3), the number of protons $N_p$ passing through the target is more conveniently expressed by integrated beam charge $Q$ divided by unit charge $e$ of the particles. Indeed, $Q$ is usually a measurable quantity (see section 2.4.3).

The capability of performing a fully quantitative analysis with PIXE in essence derives from Equation (3).

In a thin target, for any given element the X-ray production cross-sections are constant throughout the target (because the beam energy loss is negligible, i.e. all interactions happen at the same proton energy, say $E_0$), and the number of detected X-rays is a well-defined fraction of those produced (isotropic emission of all X-rays). From Equation (3), one obtains the number $Y_0$ of X-rays from the element $Z$, detected during a measurement, simply by taking the overall detection efficiency into account. The latter is the product of a geometrical factor (related to the solid angle $\Omega$ covered by the detector) and of an intrinsic efficiency $\varepsilon_{det}$, a function of the X-ray energy (and therefore of $Z$) depending on the detector characteristics (section 2.6.1):

$$Y_{0X}(Z) = \sigma_X(Z, E_0) \frac{\Omega}{4\pi} \varepsilon_{det} N_{Av} \rho Z t \frac{Q}{A e}$$

Figure 6 K- and total L-ionization cross-sections (in barn; 1 barn = $10^{-28}$ cm$^2$) for some elements versus proton bombarding energy. The displayed values are an ECPSSR calculation, which however is quite representative of the reference values from a compilation of the available experimental data. (Reproduced by permission from Johansson and Campbell.[2])
Equation (4) can be reorganized as follows (Equation 5):

\[ Y_0X(Z) = \left( \sigma_{X}(Z, E_0) \frac{\Omega}{4\pi} \frac{\varepsilon_{\text{det}}}{Ae} N_{A\nu} - \frac{Q_{\rho Z t}}{D} \right) \]

or (Equation 6):

\[ Y_0X(Z) = \eta Q_{\rho Z t} \]

by defining an efficiency factor \( \eta \) for the given X-ray, beam energy, detector and geometry (Equation 7):

\[ \eta = \eta(Z) = \sigma_{X}(Z, E_0) \frac{\Omega}{4\pi} \frac{\varepsilon_{\text{det}}}{Ae} \]

From Equation (6) it is easily seen that – provided \( \eta \) is known – the areal density \( \rho_{\rho Z t} \) for a given element can be obtained by measuring the corresponding X-ray yield on the detector and the integrated beam charge on the target. Knowledge of \( \eta \) is in principle possible even in absolute terms, because the physical factors in Equation (7) are either known (\( \sigma \), see above) or measurable (\( \Omega, \varepsilon_{\text{det}}, \) see section 2.6). In practice, rather than relying on the absolute knowledge of the terms in Equation (7) for determining the efficiency factors \( \eta(Z) \), the latter are obtained experimentally through Equation (5) itself. This is performed by bombarding a series of thin standards containing known quantities \( \rho_{\rho Z t} \) of the various elements, and measuring the corresponding X-ray yields and the integrated beam charge. The measurements on the standards must be performed using exactly the same geometry, with the same absorption layers (if any) and at the same beam energy as on the samples. The analytical procedure for the determination of elemental concentrations in unknown thin samples is therefore a relative procedure.

Figures 7 and 8 show the curves for the efficiency factor as a function of X-ray energy (i.e. \( Z \)), for the K and L series, respectively, in a typical detector geometry. As a result of the very large variation of X-ray production cross-section over \( Z \), the efficiency factor in a given geometry also spans a wide range of values, drastically decreasing for the detection of X-rays of higher-\( Z \) elements within the same series. In addition, the intrinsic efficiency of Si(Li) detectors progressively drops at X-ray energies above 20–25 keV, which corresponds to K-series X-rays of elements around \( Z = 50 \). This would create a loss of sensitivity to the detection of heavier elements; the problem is to a large extent overcome by the fact that L-series X-rays (produced with much larger cross-sections, see Figure 6) can be used as markers of their presence. At these values of \( Z \) the L-series X-rays are well within the useful range for an Si(Li) detector (see section 2.6.1), and this holds true for L-series X-rays up to the highest \( Z \) values. It will also be seen that in the higher-energy region of the spectrum the background is much lower, thus improving detection of weak lines. Further expedients to make detection limits more homogeneous through the widest possible range of \( Z \) are discussed in section 2.6.3.

2.2.2 Nonthin Specimens

Before seeing how quantitative analysis may be performed in the general case, it is useful to consider more carefully what “thin” and “nonthin” mean for PIXE analysis. The two physical effects that concur to determine whether a specimen is nonthin as far as PIXE analysis is concerned are:

- the beam energy loss while penetrating the sample;
- the self-absorption of X-rays produced in the interior of the sample.
A sample is thin if one may neglect these effects (the so-called matrix effects) and assume therefore:

- that all interactions happen at the same beam energy;
- that X-rays produced by the beam inside the target, emitted within the acceptance solid angle of the detector, have negligible probability of being lost to detection due to interactions inside the sample material itself.

By the expression ‘‘thin sample’’, we mean that the quantitative results obtained from its PIXE analysis by neglecting matrix effects are correct. Of course, this is never absolutely true and the validity of the thin-target approximation depends on the degree of accuracy one is looking for. Another important fact to bear in mind is that the thickness below which a sample may be considered thin depends both on its composition and on the X-ray energy that is observed (i.e. on the element, the abundance of which one is quantifying). Indeed, both beam stopping power and X-ray attenuation due to self-absorption depend on the average Z of the material; X-ray attenuation also strongly depends on the X-ray energy, increasing dramatically with decreasing X-ray energy. As a result of the latter point, a given physical thickness may be still considered ‘‘thin’’ as far as detection of a higher-energy X-ray is concerned, whereas it is already “nonthin” for the detection of a lower-energy X-ray from a lighter element. Approximately below 10–20 µg cm⁻² a sample of a medium-Z matrix can be assumed to be thin (to about 1% or better) for the quantification of all elements usually detected in PIXE (X-ray energies above 1 keV, corresponding to Na Kα). For the detection of higher-Z elements, detected through X-rays in the energy range above 6–7 keV, even a thickness of 2–300 µg cm⁻² might be considered thin.

When the sample thickness is such that the consequences of beam energy loss and X-ray absorption cannot be neglected, the extraction of quantitative information from the X-ray intensities in PIXE spectra is more complicated, but can still be dealt with. Indeed, both the physics of beam particle–target atom collisions, producing the energy loss, and that of X-ray interactions, producing the self-absorption effect, are well known and can be properly taken into account. The X-ray yield is obtained by integration of the contributions from the different depths inside the target. For each of them, one has to consider the proper X-ray production cross-section (which is a function of E_p and therefore of the depth from surface) and the reduction in the detected X-ray intensity, which also depends on the depth at which they are produced, because those X-rays produced deeper in the sample are more affected by self-absorption.

The detected X-ray yield for a given element is obtained by the following generalization of Equation (4):

\[
Y_{X_j}(Z) = \frac{\Omega}{4\pi} e^{\frac{-T}{\delta}} \frac{Q N_{X_j} \rho Z}{A} \int_0^T \sigma_{X_j}(Z, E_p) e^{-\mu_x E_p} dx
\]

In Equation (8) T is the finite thickness of the sample and the exponential term accounts for the self-absorption of X-rays produced at a general depth x from the surface. The X-ray intensity attenuation coefficient µ is a function of the matrix composition and of the X-ray energy. The usual detection geometry (Figure 9) has been assumed in Equation (8), where θ is the angle at which the detector is placed with respect to the target normal.

In Equation (8), one should consider that x and E_p can each be expressed as a function of the other through the beam mass stopping power S = dE_p/ρ dx (a function of the matrix composition and of E_p). Equation (8) can therefore be expressed as Equation (9),

\[
Y_{X_j}(Z) = \frac{\Omega}{4\pi} e^{\frac{-T}{\delta}} \frac{Q N_{X_j} \rho Z}{A} \int_0^T \sigma_{X_j}(Z, E_p) e^{-\mu_x E_p} dx
\]

where E_0 is the initial beam energy (at target entrance) and ΔE is the total beam energy loss through the target thickness T (Equation 10):

\[
\Delta E = \int_0^T S dx
\]

In general, for any X-ray, a matrix correction factor F_{X_j} is introduced, defined as the ratio between the ideal yield Y_0 that would be obtained from the same target, in the absence of matrix effects, and the actual yield Y.
target becomes infinite much before the condition is fulfilled.

By recalling Equation (6) for $Y_0$, Equation (11) implies (Equation 13):

$$ (\rho t)_Z = \frac{Y_X(Z)}{Q_{\eta E_0}} F_X(Z) $$

where $\eta$ is the efficiency factor, resulting from the measurements on thin standards at the surface beam energy $E_0$. In principle, therefore, the quantitative analysis of nonthin samples can be obtained from the detected yields $Y_X(Z)$, by considering the samples as thin (use of thin target efficiency factors) and then applying the proper correction factors $F$ to account for matrix effects.

The problem remains as to how to obtain proper correction factors. This is a prior a problem, but can be solved quite well in many cases, such as when analyzing a homogeneous target of known thickness. The equivalent to the exact knowledge of target thickness $T$ is a much more frequent case than might be thought at first sight. In fact, whenever the thickness, although unknown, is larger than the proton range $R_p$ (of the order of 50–100 $\mu$g cm$^{-2}$), for the calculation of $F$ it can be replaced by $R_p$ itself, or by any larger value. In this case one talks about “infinitely thick” targets, where of course this term only implies that $T > R_p$. Even before this limit is reached, at least for the lower-Z elements, the exponential term in Equations (8) and (12) may be so small after a certain depth that the expression under the integral goes to zero and contributions from deeper layers can be neglected. In simple terms, for the lower-Z elements the dominant matrix effect is self-absorption rather than the decrease in production cross-section due to the beam stopping down; their X-rays continue to be produced at depths from which they will not reach the detector due to the self-absorption effect. Actually, as far as the detection of lower-Z elements is concerned, the target becomes infinite much before the condition $T > R_p$ is fulfilled.

It is also necessary to make an assumption about the matrix composition to evaluate the integral in Equation (12), because both $\mu$ and $S$ are matrix dependent. If this composition is not known, as is usually the case in analytical work, the adopted technique then becomes an iterative procedure. The zeroth-order approximation of the matrix composition is obtained by neglecting all the matrix effects, i.e. by using Equation (13), with $F(Z) = 1$ for all values of $Z$. The matrix composition obtained by the areal densities thus deduced for the detected elements is then used to compute the stopping power and absorption coefficients to be used in Equation (12). From that, a first-order approximation of the matrix composition is obtained by reworking Equation (13), and this composition is then used again to compute the stopping power and absorption coefficients to be used in Equation (12), and so on iteratively. The procedure rapidly converges and a good estimate of the actual composition can be given. Two aspects must be pointed out in this respect.

First, the assumption is made of a homogeneous composition as a function of depth through the explored depth range (recall that we are talking about tens of micrometers at most). However, this assumption may be completely wrong, and the only way to check its validity is to perform further independent analyses with other techniques (or even simultaneously with other IBA techniques, or performing subsequent PIXE runs at different proton bombarding energies).

Second, the various approximations of the matrix composition, if based on just the PIXE-detected elements, can be largely defective because very light elements are hidden from the analysis (typically, this happens for $Z < 11$, but the actual limit depends on the specific setup). The undetected fraction can be important and affects the actual matrix effects, which depend on all the elements present in the material. In many practically important circumstances the undetected fraction may be known independently, on the basis of separate measurements such as simultaneous measurements with other IBA techniques. In other cases, it can be indirectly deduced by the concentrations of the detected fraction itself; this is the case for instance in the analysis of rocks of volcanic origin. Here all elements can be considered to be present in the form of oxides, so that each element bears an amount of oxygen in a well-defined proportion to the detected element’s abundance. Under these circumstances, the undetected fraction is well estimated and a good approximation of the whole matrix composition can be used to compute the factors $F$ from Equation (12). Finally, it should be remembered that both the stopping power and the absorption coefficients depend on the matrix composition, but not so dramatically as to alter significantly the final values obtained by the iterative procedure of Equation (12) if a minor change in the matrix composition assumption is made. Obviously, this affects the different elements in a different manner: as a rule of thumb, lighter elements are more affected by incorrect assumptions about matrix composition. As for any other quantitative analytical technique, it must be
kept in mind here that the more unverified assumptions are made, the less accurate may be the final quantitative result.

If the sample thickness is larger than about 50 μm, the uncertainty about its value is irrelevant, because from the point of view of PIXE this is actually an infinitely thick target for the quantification of all elements. However, for a target of an intermediate unknown thickness, the quantitative analysis becomes problematic because, in principle, there may be different combinations of composition and thickness leading to the same detected X-ray yields. Some independent guess often may be made on either of the two, thus leading to reasonable results also in this case; however, it must be stressed that this remains the hardest situation to deal with for an accurate quantitative analysis.

2.3 Minimum Detection Limits in PIXE Analysis

A high value of the efficiency factor \( \eta \) for a given element, leading to large statistics for the corresponding X-ray peak in the PIXE spectrum (Equation 6), is obviously important for a sensitive determination of that element. However, this is not the only requisite, as the MDL depends on the signal-to-noise ratio.

In general, the performance in terms of the MDLs improves for any analytical method when the signal is detected with higher efficiency and when the noise is low. Because the cross-sections for the production of X-rays by accelerated particles are high, the number of X-rays produced by PIXE per unit quantity of a given atomic species is large. This means that the signal is good. The noise from which the signal must emerge is, in the case of PIXE (as well as in any other spectroscopic technique), the continuous background in the spectra. As can be seen in Figure 2, a continuous background is actually present in the X-ray energy spectra from a PIXE measurement, and characteristic X-ray peaks must be discriminated from the statistical fluctuations of this background. Let us therefore examine in some detail the reasons for the presence of this continuous background and the possibilities for the operator to reduce it.

2.3.1 Background in PIXE Spectra

There are several physical reasons for the presence of the continuous background in the PIXE spectra.

In the lower-energy part the continuous spectrum is higher and arises mainly from atomic electrons ejected by the interactions of the beam particles with the target. During their stopping down within the target, these electrons emit BS radiation. This is a consequence of a basic law of electromagnetism, that when a particle bearing electric charge undergoes an acceleration, it emits energy in the form of electromagnetic radiation. The intensity of the emitted BS is proportional to the square of the acceleration; its energy has a continuous spectrum extending up to the initial energy of the emitting particle. The electron BS in the lower part of the PIXE spectrum is called secondary BS, as opposed to the primary BS produced directly by the protons in their stopping down. It is easy to understand that:

- In PIXE, secondary BS has a much higher intensity than primary BS, which is essentially negligible. The forces responsible for both proton and secondary electron acceleration have equal intensity (being the Coulomb forces of interaction with atomic electrons) but the mass of protons is much larger than the mass of electrons. The proton acceleration and the corresponding BS intensity are consequently much lower.
- The maximum energy of the secondary BS is in the ratio 4\( m_e \) : \( M \) to that of the incident particles (with \( m_e \) and \( M \) being the electron and proton mass, respectively), this being the maximum energy transfer from incident particles to free electrons. Indeed, the maximum velocity acquired by the electrons, occurring for central collisions, is equal to twice that of the incident particles, so that Equation (14) holds:

\[
E_{\text{max},e} = \frac{1}{2} m_e 4v_p^2 = \frac{4m_e}{M} \frac{1}{2} M v_{p}^2 = \frac{4 m_e}{M} E_p
\]

In the case of protons, the maximum energy value of the secondary BS is therefore around 4.3 and 6.5 keV for \( E_p = 2 \text{ MeV} \) and 3 MeV, respectively. Consequently, under typical measuring conditions the background due to BS is practically zero in the higher part of the energy spectrum, i.e. the region of the X-ray lines used for the quantification of medium- and high-Z elements. This is the region where X-rays are produced with lower cross-sections by PIXE. Therefore, where the signal is lower, the noise is fortunately lower also, and good MDLs are preserved. Many studies (both theoretical and experimental) have been carried out on the physics leading to the BS emission in PIXE.(20,21) An important practical feature is that BS emission is not isotropic, but has a maximum at around 90° to the beam direction. Therefore, to improve the performance in terms of MDLs, one should avoid placing the X-ray detector at around this angle. The most frequently used geometry is with the detector as backwards as possible to the beam direction, typically at 135° or more.

Some background continuum exists even in the higher energy part of the PIXE spectrum. It originates mainly from the Compton interactions of the higher-energy gamma rays produced by the incident particles either
The composition of the target itself and of the detector material and active volume. It increases with increasing Z and this is one reason why silicon detectors are in general preferred to germanium ones. As far as the detector’s volume is concerned, in the range of detector sizes that are used, larger ones produce a higher Compton background because of an increased probability of gamma ray interactions within their volume.

- The composition of the target itself and of the other materials with which the beam particles can interact. For low-Z materials, nuclear interactions with the beam protons are much more probable due to the closer approaches of the protons to the target nuclei, which in turn derives from the lower Coulomb repulsion. At the proton bombarding energies used in PIXE, most nuclei of low-Z elements can be excited inelastically and emit as a consequence gamma rays, which produce the Compton background in the PIXE spectra. The intensity of such emissions depends on the element, but also on the thickness of the emitting material and beam energy, due to the existence of resonances in the nuclear interaction cross-sections. Under typical conditions, fluorine and sodium are the elements giving rise to the higher gamma ray yield.

The Compton background arising from the production of gamma rays of elements within the target is unavoidable and the only expedient to lower it is to avoid the presence of unnecessary material around the detector, to decrease the probability of Compton scattering of the gamma rays in the surrounding materials. More can be done instead to decrease the contribution due to gamma rays originating from primary beam interactions on materials other than the target itself. First, low-Z materials such as aluminum should be avoided as constituents of chambers, collimators, scatterers, exit windows (in external beam set-ups), etc. Second, the points along the beam path that may constitute possible gamma ray sources arising from beam interactions should be effectively shielded towards the X-ray detector.

2.3.2 X-ray Line Interference
In addition to the presence of the continuous background, there is another factor that may worsen – in specific circumstances only – the MDL of some elements. This problem is common to all analytical techniques based on X-ray spectrometry (i.e. also XRF and EPMA) and it is recalled here just for the sake of completeness. This limiting factor consists of energy overlaps between X-rays originating from different elements. When the energy difference between two X-rays is much smaller than the detector resolution, they can hardly be discriminated by the spectra deconvolution codes. If one of the two elements giving rise to the overlapping X-rays is present in much larger abundance than the other, it can mask the presence of the weaker one even in the case of somewhat larger energy differences, within the tails of the strong peak. Thus, the possibility of detection of the weaker line is considerably worsened. Examples of this problem are:

- Kα lines of element Z with Kα of element (Z + 1), for
\[ 20 < Z < 30; \]
- K line of Na (1.041 keV) with L lines of Zn (1.020 keV);
- K line of Mg (1.254 keV) with L lines of As (1.282 keV);
- Lα line of S (2.308 keV) with M lines of Pb (centroid at 2.346 keV) and to a lesser extent with those of Hg (centroid at 2.224 keV);
- Kα line of Ti (4.509 keV) with Lα lines of Ba (centroid at 4.465 keV);
- Kα line of As (10.532 keV) with Lα lines of Pb (centroid at 10.551 keV).

When the interference between two lines cannot be safely deconvoluted, the quantification of the two elements must be done on the basis of other lines of their spectra. This often implies that minor-intensity X-ray lines come into play and the MDL for the corresponding element increases.

2.3.3 Minimum Detection Limits
In the light of all the above considerations concerning high X-ray production cross-sections and detection efficiencies, and low continuous background in the energy spectra, it turns out that PIXE is basically a very sensitive technique. Figure 10 gives an idea of the MDLs of PIXE under typical analytical conditions. It should be emphasized that this is just a general indication, and that in any given analytical situation the actual MDL for a given element may be different. The MDL can depend on specific features of the sample under analysis, such as whether it is thinner or thicker, or the specific matrix material. Experimental conditions also have an
effect: beam energy, beam current intensity, and total time of target exposure to the beam all affect the analytical performance in terms of the MDL. Under certain circumstances, the attainable MDL can be much better than suggested by Figure 10. An example is when searching for ultratrace elements of medium Z in a very low-Z matrix. The opposite occurs in the presence of a high abundance of elements that give rise to X-rays interfering with those of the elements searched for.

When dealing with MDLs, both relative (in terms of minimum detectable mass over the total mass of the sample) and absolute values should be considered. Indeed another great quality of PIXE is that absolute quantities as small as picograms of the elements in the detectable range can be quantified in measurements lasting only a few minutes. This makes PIXE a very useful technique when nondestructivity is a mandatory requirement (as in the case of precious items such as works of art), or when the quantity of material to be analyzed is very small (as in some applications related to environmental pollutants).

2.4 Ion Accelerators and Sample Irradiation

2.4.1 Beam Production and Transportation

Most of the particle beams for PIXE analysis are produced by small Van de Graaff accelerators, with maximum terminal voltages of 2–4 MV. Accelerators of this kind often exist in nuclear physics divisions of universities or other research institutions, being the equipment used for nuclear spectroscopy studies in the 1960s and 1970s. In these situations the initial cost of setting up centers for IBA and specifically PIXE has been limited to the dedicated irradiation chambers (or the specimen holders for external set-ups, see below) and to the detection systems, which are not especially expensive. This certainly favored, in the 1980s, the start-up of PIXE activities in many laboratories. However, these accelerators are becoming less supported by their manufacturers. A new generation of small electrostatic accelerators (based on voltage generators of both Van de Graaff and Cockroft-Walton type) have been installed in some laboratories either to replace older ones or to start up new PIXE (and other IBA) activities. Most of these new accelerators are of the tandem type. In tandem accelerators, two acceleration tubes are placed on opposite sides of the positive high-voltage terminal, located in the center of the machine, inside a tank which is gas filled at high pressure (this is needed to avoid voltage discharges to ground). The ions are produced by an external negative-ion source and then injected into the first acceleration tube from the low-voltage side. After acceleration to the positive voltage terminal, the ions undergo a charge inversion through the stripping of the outer electrons (produced by passing the beam through proper thin carbon foils or gas flow), so that they are further accelerated in the second tube towards ground. In this way, a lower terminal voltage is sufficient to produce a beam of sufficient energy. For instance, with a 2-MV tandem, proton beams up to 4 MeV, or α-beams up to 6 MeV can be produced. Further advantages of tandems derive from the presence of the external ion source (contrary to the case of single-ended electrostatic accelerators, where the ion source must be on the high-voltage terminal inside the high-pressure tank).

With different sources, it is possible to accelerate any kind of ions, including the heavier ions that may be used for other IBA techniques. In addition, one can perform accelerator mass spectroscopy (AMS) for the search of ultratrace elements or rare isotopes in a sample. For this purpose, the sample is used as the material to be ionized in the source; the best-known case is the quantification of 14C for archaeological dating. Together, these factors have initiated start-up of several new laboratories (or the modernization of previously established ones) based on tandem machines, where both PIXE and other ion-beam-based applications are performed.

In standard PIXE, the beam from the accelerator is led to hit the sample by conventional beam transportation systems, mostly based on magnetic deflection and focusing. The typical energy stability of beams produced by this kind of accelerator is quite good, with a residual voltage ripple normally less than 1 kV rms at maximum voltage. For PIXE applications this is not a real need, however, because the trend of X-ray production cross-sections with beam energy is rather smooth. Also, the beam currents that the accelerators might produce (up to tens of microamps) are not exploited, due to the large value of the production cross-sections. Typically, PIXE measurements are performed at beam current intensities of 20–30 nA at most (but much less than 1 nA for certain applications in which precious samples might otherwise be damaged by a more intense beam; see section 3).
Thus, in both respects (energy stability and current intensity) the accelerator performance is never a limitation for standard PIXE. This is less true for micro-PIXE set-ups, in which a much higher beam brightness is needed and high energy stability is at a premium. However, the standard performance of typical accelerators is already adequate for micro-PIXE; thus, a new accelerator of special design is not required just to implement a micro-PIXE facility.

The beam transportation line is obviously under vacuum. Typical values are around $10^{-6}$ mbar, although worse vacuum levels may be tolerated for PIXE applications (but not for micro-PIXE). Visual inspection of the beam cross-section is often provided along the beam line by retractable quartz viewers, whose fluorescence is observed through viewports by means of TV cameras. This makes the tuning of focusing and deflection systems much easier. For the same purpose, retractable Faraday cups are often available at critical points along the beam line.

The beam cross-section at the target may need to be either as small as possible (for a microbeam, section 2.5), or larger so as to average over a wider area of interest, which may be even some tens of square millimeters. In the latter case, it is necessary to have a uniform distribution of the beam current intensity over the probed area, in order to correctly average out inhomogeneities in the target composition.

A uniform beam current density can be achieved in several ways. One possibility is to pass the beam through a thin metal foil (some hundreds of micrograms per square centimeter) placed one or two meters upstream. Then the multiple small-angle scattering within the foil widens the angular aperture of the beam, and an adjustable collimator picks up its central, homogeneous part over the desired size. A side effect with this technique is an energy loss and straggling of the beam, but this is not a problem in PIXE and can be perfectly taken into account in the quantitative analysis.

Alternatively, the beam may be defocused by untuning the magnetic quadrupoles present on the beam line for focusing, and then collimating close to the target. Although this technique is simpler, it is less effective because it is difficult to monitor the actual homogeneity of the beam intensity over the selected area. A third method uses a well focused beam, and rasters with an $x$-$y$ scan over the selected sample area. The disadvantage of this technique is that, in the presence of target inhomogeneities, the X-ray count rate from the different parts may vary considerably during the raster. Consequently, the pile-up corrections in fitting the PIXE spectra (section 2.6.2) may become problematic, as the corrections applied by the data reduction software are based on the assumption of a time-uniform count rate.

All collimators along the beam transportation lines are generally made in materials producing no detectable X- or gamma rays. Tantalum is the usual choice far from the target point because of its good dissipation of the heat generated by beam stopping. The production of K-series X-rays (around 60 keV) and of gamma rays due to Coulomb excitation of the nucleus is not intense, whereas copious L X-rays produced are easily absorbed by placing lead shielding in the line of sight to the detectors. Close to the target, the preferred material is graphite, which does not emit X-rays if sufficiently pure.

### 2.4.2 Irradiation Chambers

In conventional PIXE, irradiation is performed with the sample in vacuum. This is a limitation in several important kinds of application, such as when large samples are to be analyzed and taking samples of material is not allowed, or when keeping a specimen in vacuum could alter its composition. To overcome these problems, many laboratories have implemented external beam irradiation facilities (section 2.5).

The irradiation chamber is often made in aluminum, for economical reasons, but this material is not best suited because of its relatively high cross-section for the production of gamma rays. The regions of the chamber (as well as of the interior of the beam line) that are exposed to the beam (due to scattering) should be lined with nonemitting materials, such as ultrapure graphite.

Most chambers have a multisample capability in order to make the analysis faster. More or less sophisticated means of automatic sample changing are available. Usually a glass window allows the operator to view the samples inside the chamber with a video camera, both during sample changing and during irradiation, to check sample integrity under the beam.

The usual detection geometry is with the X-ray detector as backwards as possible, because the secondary BS is lower (section 2.3.1). The X-ray detector may be placed outside the vacuum chamber, viewing the sample through a window made as thin as possible so as to limit absorption of low-energy X-rays. Alternatively the detector cryostat may even be incorporated within the chamber, sometimes with the possibility of a windowless geometry based on a sliding vacuum seal (section 2.6.1). A means of inserting a variety of X-ray absorbers of different thickness and material must be provided, to enable changes to the detection efficiency curve versus X-ray energy according to the specific analytical demands of the experiment (section 2.6.2).

Additional detectors are often present in the chamber to complement PIXE analysis with the simultaneous use of other types of ion-beam-based techniques. These usually include one or more surface barrier silicon detectors.
with which to implement backscattering spectroscopy. When using protons as projectiles, it is not always safe to assume “Rutherford” elastic scattering as valid, i.e. cross-sections may not always be computed from purely Coulomb projectile–nucleus interactions. In the proton elastic scattering on light-Z elements, the effects of the nuclear force on cross-sections may be nonnegligible or even dominant, due to the close approaches that can take place between protons and target nuclei. In spite of this, however, useful quantitative information can be extracted (corroborating and sometimes adding to that obtained by PIXE), provided that experimental data (including the nuclear interaction effects) are available for the cross-sections. Inelastic scattering can also provide useful information. A germanium detector may be faced to the irradiation chamber for the simultaneous detection of gamma rays: PIGE. Because gamma ray energies are much higher than X-ray energies, and consequently the absorption of electromagnetic radiation is not a problem, the germanium detector need not be placed inside the chamber.

2.4.3 Measurement of Beam Current and Charge Integration

During an irradiation, it is important to monitor the beam current because the sample may be damaged if safe levels of intensity are not maintained. The safety level varies with sample types, being much lower in general for electrically and thermally nonconductive materials.

Equally important is accurate integration of the beam current during each run, as this is often a fundamental parameter for correct quantification of the obtained data (see Equations (3), (6), and (13)).

With thin specimens that allow the beam to pass through them with negligible energy loss, the traditional technique may be used of both measuring and integrating the beam current in a Faraday cup. The cup must be obviously insulated from the beam line. The cup material or lining must be such as to avoid emission of detectable X- and gamma rays, for the same reasons given above for the materials of beam line, collimator, and irradiation chamber. Typically graphite is used. Care should be taken that the cup receives all the particles that have traversed the beam; with samples of intermediate thickness, a relevant overall scattering may occur and the Faraday cup geometry must ensure an adequate acceptance angle.

Also, the phenomenon of secondary electron escape from the cup may be relevant, which could give rise to an overestimate of the actual beam current. To prevent this effect, a negatively charged ring may be used as a guard electrode at the entrance to the cup, to reject outgoing electrons. Alternatively they can be deflected and thus recollected through the use of small magnet assemblies (electrical bias and small magnets will not affect the much heavier and energetic incoming particles). An accuracy as good as 1% can be achieved through the use of good-quality current meters and charge integrators.

With thick samples that stop the beam, the current must be measured and integrated on the sample itself, which requires the samples to be made electrically conductive if not already so (in order to avoid sample charging and consequent abrupt discharges). This may be achieved by a thin surface carbon coating, as in the case of EPMA. Secondary electrons escaping from the sample may be a much more relevant effect than with Faraday cups, due to the open geometry; they must be recollected by using a negatively biased suppressor electrode at a few hundred volts potential. Alternatively, the target itself may be positively biased with respect to the chamber.

With thick samples – or even with samples of intermediate thickness, causing a large scattering of the beam – alternatives to the Faraday cup may be used to measure the beam current. A thin self-supporting foil can be inserted along the beam path before the sample, and the count rate of backscattered particles, measured by a proper particle detector, can be taken as an indirect measurement of beam current intensity. Alternatively, the yield of some other interaction product of the beam particles with the foil material – such as X-rays themselves – may be used as an indicator of the beam current. In some external beam set-ups, the beam line exit window itself is used. When using such procedures, the problems of correct quantification of the current connected to secondary electron emission are completely overcome. After a calibration they may even provide a good absolute measurement of the current, provided that the metal foil does not change its thickness during irradiation due to beam-induced damage. A variant of this method is to measure the yield of backscattered particles (or other beam-induced radiation) on a rotating vane intercepting the beam at a sufficiently high frequency that, at the end of the measurement, the current sampling procedure is significant. Typically, 1 Hz is sufficient since run times are of the order of minutes.

2.5 External Beam Set-ups

An increasingly popular variant of conventional PIXE is external or “in-air” PIXE. This, as well as other IBA techniques, can be performed simply by passing the particle beam through a thin window, thus hitting the sample in its natural environment. The beam size can be determined by an aperture in the last section of the beam path within the vacuum, whereas the X-ray detectors are external. The sample is placed a few millimeters from the window and, by using a positioning stage (sometimes with micrometric control), can be moved in the plane.
perpendicular to the beam for selective analysis. The external environment is often saturated with helium, to reduce beam energy loss and straggling with respect to air. The helium may be simply flooded in front of the exit window, with no containment, or be held in a simple closed environment. The use of helium has the further significant advantage that the transmission of low-energy X-rays is much higher than in air, which increases the possibility of detecting lighter elements. As an example, more than 96% of the 1.04-keV K X-rays of sodium are still transmitted when traversing 3 cm of helium, whereas for a similar distance in air the transmission would be only $2.4 \times 10^{-6}$; for the X-rays of sulphur (2.31 keV), the transmissions in 3 cm of helium and air are 99.7% and 28%, respectively. A disadvantage is that helium can penetrate the thin beryllium window of the Si(Li) detectors (section 2.6.1). This produces a progressive worsening of the vacuum levels inside the cryostat, which may necessitate a pump and bake procedure, typically after some months of use. To overcome this problem, the use of hydrogen rather than helium has also been reported (detector windows are much less permeated by the hydrogen molecules), but has not gained popularity for the fear of accidents due to its inflammability.

Figure 11 is a sketch of a simple external beam set-up, with helium flooding in an unenclosed environment and two Si(Li) detectors.

Topics relevant to external beam analysis have been reviewed in several articles.\(^{23-25}\)

The main advantages of an external beam set-up are:

- ease of handling and changing of the sample – even large objects may be analyzed, and the specimen positioning is not problematic;
- drastically reduced risk of beam-induced damage to the sample – the problems of local heating are much smaller, especially when using a helium flow, which is a very efficient heat remover;
- electrical charging of insulated samples does not occur – this avoids the need for surface coating by graphite, as is usually done with samples in vacuum;
- ease of installation and change to the set-up (type, number and position of detectors, tilting angle of the sample, provisions for monitoring camera, etc.).

The first three of these points have encouraged the use of external beam set-ups for the analysis of fragile and/or precious objects, such as items of artistic, archaeological, and historical interest (sections 3.4 and 3.5). However, the external beam set-up is advantageous for most PIXE applications. Only for applications requiring a microbeam below about 10–20 µm is the external beam set-up not appropriate. Indeed, the scattering in the window and in the external path produces a beam halo. Thus, even with the best focusing, the actual beam spot size on the target cannot be smaller than a minimum value (depending on several factors, mainly the distance travelled by the beam in atmosphere). Some inconvenience with an external beam may also arise for other IBA techniques, such as Rutherford backscattering spectroscopy (RBS) or nuclear reaction analysis (NRA), when operated simultaneously with PIXE. As in those techniques the accuracy of the analytical information is directly related to the beam energy, the energy straggling due to the exit window and to the residual path in the atmosphere worsens the quality of the data obtained. However, in the late 1990s thinner beam exit windows have become available (see below). This, and the use of helium outside the window, has enabled the advantages of the external beam set-up to be retained without excessive drawbacks.

In external beam set-ups, the exit windows for the beam must be mechanically strong enough to sustain the pressure drop from the vacuum environment of the accelerator beam lines to atmosphere, and also exhibit a high resistance to radiation damage. Certain materials, such as Mylar\(^\circ\), which are mechanically strong enough, cannot tolerate even weak beams without early rupture. A typical material for beam exit windows is Kapton\(^\circ\), a polymer of composition \((C_{22}H_{10}N_{2}O_{4})_n\). At a thickness of 8 µm, Kapton\(^\circ\) typically withstands a beam of 10 nA with a cross-section of 1 mm\(^2\) for 2–3 days, after which a change of the window is a wise precaution. The energy losses in
8 µm of Kapton® are 90 keV and 125 keV, respectively, for 3 MeV and 2 MeV protons; the fwhm energy straggling is about 20 keV (uncorrected Bohr estimate). Further energy loss and straggling before hitting the target are typically of the same order in air, or much smaller in helium. The overall values for both the energy loss and straggling (the former sum up linearly, the latter combine quadratically) are therefore of little consequence to PIXE, due to the smooth trend of X-ray production cross-sections with beam energy. Therefore, the possibility of a quantitative analysis is fully retained with external PIXE.

Another material sometimes used for exit windows is aluminum (about 10 µm thick), with a durability of months before changing the window. However, a higher continuous background is produced in the spectra due to beam-induced gamma rays from the window. Its use is therefore not recommended when bombarding very thin samples, where the X-ray yield is relatively weaker. With thick samples, an aluminum window may be a good choice.

The successful use of ultrathin windows of Si₃N₄, available down to a thickness of 0.1 µm, has been reported. This material exhibits a very high resistance to the beam and the thin foils still withstand the pressure drop for a surface area of a few square millimeters. It has been employed therefore to extract focused proton microbeams down to 20 µm, with negligible halo due to the extreme thinness and to a very compact geometry with the specimen quite close to the window, in a helium atmosphere.

### 2.6 Detection of X-rays, Data Acquisition and Reduction

#### 2.6.1 Working Principle and Characteristics of Si(Li) Detectors

Typical detectors used in PIXE are lithium drifted silicon crystals acting as diodes. In these solid-state nuclear detectors a free charge-depleted volume is created on one side of the junction by applying a reverse bias with a convenient high voltage power supply (some hundreds of volts, up to 1 kV). The ionizing radiation that interacts in this volume produces free hole–electron pairs that are promptly swept by the electric field – due to the voltage bias – towards the collecting electrodes. As the number of electron–hole pairs created inside the active volume is proportional to the energy release of the ionizing radiation (an average energy value of 3.6 eV is needed to create a hole–electron pair), the total charge collected on the electrodes is also proportional to the released energy. The current pulses through the detector produce, at the preamplifier output, voltage steps of amplitudes proportional to the energy releases. These voltage signals, when appropriately amplified and shaped, are then amplitude-analyzed to construct the detected X-ray energy spectra (section 2.6.2).

The Si(Li) detectors must work at a low temperature (typically −170 °C). Otherwise, when voltage biased, the inverse current of the diode (increasing exponentially with increasing temperature) would damage the detector itself and/or the first stage of signal preamplification. In particular, the compensation due to the presence of the drifted Li ions might be lost in a short time due to their mobilization (induced by the electric field). Si(Li) detectors can instead be safely stored at room temperature when they are not under bias. Protection circuits should always be used (and are indeed available in modern detectors) to prevent the high voltage supply from actually applying the bias until a sufficiently low diode temperature is reached.

Because of the need for a low operation temperature, the crystals are kept inside a cryostat under vacuum and cooling is typically achieved by conduction through a cold finger kept in contact with liquid nitrogen in a Dewar. The option of a Peltier cooling system is also available, which makes the assembly much more compact at the expense of less-effective cooling (which implies a slightly worse energy resolution). A vacuum is first created in the cryostat at time of manufacture. A proper amount of molecular sieves, in thermal contact with the cold finger within the cryostat, passively maintain a sufficient level of vacuum when the detector is cooled. In general, this situation may be maintained for several years, after which servicing (pump and bake procedure) is needed to restore the vacuum.

The cryostat wall in front of the detector (the entrance window) must be very thin if low-energy X-rays are to be transmitted with negligible probability of being absorbed by the window itself before reaching the detector’s active volume. The window should also be light-tight because silicon detectors are photosensitive, producing a large response to ambient light. Traditional cryostat windows are made of beryllium, of a thickness down to 8 µm. They can stand the pressure drop over a surface area of about 1 cm², but they must be handled with great care because they are very fragile. Any puncture of the window may be catastrophic, with sudden ventilation of the detector’s cryostat. This in turn may have very serious consequences in that the detector system can be destroyed if the diode was under bias – the sudden vapor condensation on its surface gives rise to current paths, which may spoil the passivated surface that maintains the bias voltage. In addition, the large currents may burn the entrance FET (field effect transistor) of the preamplifier.

Typical active areas of the Si(Li) detectors are from 10 to 100 mm² and the thickness of the depleted volume is from 3 to 6 µm. As far as the intrinsic efficiency
Intrinsic efficiency of Si(Li) detectors versus X-ray energy. The three curves on the left side refer to detector entrance windows of different thickness; the two curves on the right refer to different overall thickness of the detector’s active volume. (Reproduced by permission of EG&G Ortec.)

$\varepsilon_{\text{det}}$ is concerned (see Equation (4) and the following discussion), Si(Li) detectors have a 100% intrinsic efficiency over an X-ray range from 2–3 keV to about 20 keV. This means that in this energy range an X-ray reaching the entrance window will lose all its energy in interactions inside the active volume, thus producing a full-energy peak in the spectrum. Figure 12 shows the intrinsic efficiency of typical Si(Li) detectors as a function of X-ray energy, for various entrance windows and detector active thicknesses. The detection efficiency decreases at both lower and higher energies. On the high-energy side, this is in connection with the limited active thickness of the detector – with smaller detector thicknesses and higher X-ray energies, the probability of losing all the energy within the active volume decreases. On the low-energy side, the intrinsic efficiency decrease is due to the increasing probability of X-ray absorption in the detector entrance window.

Materials other than beryllium have also been used to build extra-low absorption windows that make the detection of very light elements possible, down to carbon. An alternative when the operator wishes to extend analysis to these elements is the possibility of window removal. This option can only be used when working with an in-vacuum set-up, and through some mechanical design to allow for vacuum-tight insertion of the cryostat inside the irradiation chamber. Removal of the window can only be done once a sufficiently good level of vacuum is reached in the chamber, in order to avoid vapor condensation on the cold detector surface.

It should be remembered that the severe problems of self-absorption within the sample itself (section 2.2.2) for the very-low-energy X-rays involved in the detection of these light elements (276 eV for carbon) makes their analysis only qualitative anyway. This consideration is more critical the lower the atomic number. As a general rule, relatively good quantification can be made only when starting from Na ($E_X = 1041$ eV); however, this also depends on the kind of sample (whether it is extremely thin or not, the nature of matrix, etc.) and on the degree of accuracy required.

Besides the effect of the cryostat window, at lower X-ray energies the detection efficiency is very sensitive to any absorption layers introduced intentionally or due to dead surface layers on the detector. The latter may occur when the vacuum level inside the cryostat worsens because of small leaks – a layer of condensed vapor is formed on the front surface of the cold detector inside the cryostat. Low-energy efficiency can also be drastically reduced by purposely interposing absorption filters along the path from target to detector. For example, with a Mylar® absorber of only 10-µm thickness the transmission of the 1.04 keV X-rays of Na is 3.3%, that of the 1.74 keV X-rays of Si is 47%, that of the 2.3 keV X-rays of S is 72%, and 92% of the 3.69 keV X-rays of Ca are transmitted. With 100 µm of Mylar®, transmissions are $<10^{-14}$, 0.05%, 5.5%, and 43%, respectively, for the X-rays of the four elements. It is obvious that by using different absorber material and thickness one can drastically modify the curve of detection efficiency versus X-ray energy. As explained in section 2.6.3, this property is often exploited to make the MDLs more homogeneous over a wider range of Z.

2.6.2 Spectra Acquisition and Data Reduction

The voltage signals produced by the charge preamplifiers are first shaped and amplified to make them suitable for amplitude classification, which is the basis for the acquisition of the energy spectra. A quasi-Gaussian pulse shape is normally used, which can be synthesized by different linear networks including successive stages of differentiation and integration of the original quasistep signal from the preamplifier.

The time constant used must be long enough to allow for complete collection of the charge created by the ionizing radiation inside the active volume of the detector. Incomplete charge collection would result in the so-called ballistic deficit effect, which produces low-energy tails to the line shapes in the energy spectra, increasing linearly with peak energy. Also, because of the prevalence of series noise, long time constants favor a better signal-to-noise ratio, i.e. better energy resolution.

At the same time, the time constant should be short enough to avoid a long time occupancy of the signal baseline by the pulse, in order to make handling of higher count rates possible. For the usual quasi-Gaussian pulse shapes a baseline recovery to better than 1% is achieved in a time equal to 3–5 times the time constant.
When the average time interval between successive pulses gets smaller than about 10–20 times the baseline occupation of a single pulse, there begins to be a non-negligible increasing probability that a pulse arises before the previous one has completed its recovery to the baseline. This generates a wrong classification of the pulse amplitude (the pile-up effect) with consequent distortion of the accumulated energy spectra. Minor distortions may also be generated by imperfect tunings of the electronic chain, such as improper adjustment of the pole-zero cancellation or of the baseline active recovery circuits.

The choice of time constant is dictated by the main requirement in terms of performance (as outlined above, high count rate capability and good energy resolution are somehow conflicting). In general, a compromise between the two needs is given by a time constant value of 6–10 µs, but longer values also may be used when extremely good resolution is the main goal and the low count rate makes this possible. Of course, everything depends on the specific experimental situation – target composition and thickness, beam current, detector size and geometry, etc.

The linearly shaped pulses are amplitude analyzed by an analog-to-digital converter (ADC), which is then coupled to a computer where a distribution histogram of the digitized amplitudes is constructed. Because all the signal handling processes are linear, the histogram represents the spectrum of the radiation energy losses inside the detector. Thus, the full-energy X-ray interactions give rise to peaks in the spectrum. The energy scale of the spectrum can be calibrated by using a source of X- or gamma rays of known energies for a spectrum acquisition.

To extract quantitative information about elemental abundance in the sample, the peak areas in the X-ray energy spectra must be evaluated as accurately as possible. The various aspects of the spectrum deconvolution procedures are essential for quantitative analysis. In particular, modeling of the continuous background shape and deconvolution of peak multiplets have been widely studied. Several software packages are available to the analyst, including provisions for taking thick target matrix effects into account. Extended reviews of these aspects are available.\(^2\),\(^27\)

The first step of the process is in general the modeling of the background. As the background is higher in the lower-energy X-ray region (section 2.3.1), where in addition the X-ray density (and hence the probability of overlaps) is higher, this is the most crucial energy region to be considered. Basically, two different strategies may be adopted: the assumption of an analytical (in general polynomial) function for the shape of the continuum; and an empirical subtraction of its contribution by a smoothing–filtering procedure that eliminates the variations of the counts per channel that are slower than a preset value. To be considered as not arising from true lines, these variations must meet certain criteria, which take into account the amplitude of the statistical fluctuations and the assumed peak widths. Once the contribution of the continuous background has been eliminated by this filtering procedure, the peak areas are determined from the filtered spectra (rather than from the direct spectra).

For the purpose of the detection of peaks, even in the presence of multiplets, and of the evaluation of peak areas, two aspects are essential: (a) knowledge of the detector’s response to a single line, i.e. the peak shape; and (b) access to a complete and accurate database of X-ray energies and relative intensities for all the elements in the periodic table, so that after energy calibration the peaks can be assigned to the corresponding elements.

Considering the first point above, the line shapes of the full-energy X-ray peaks in the spectrum are basically Gaussian. The effect of electronic noise that adds randomly to the signal pulse height, and the stochastic nature of the process of electron–hole pair creation in the detector’s active volume both contribute to this shape. X-rays losing identical energies inside the active volume do not always produce exactly the same number of pairs, and this fluctuation in turn results in voltage pulses of variable amplitudes and therefore in peak widening. Due to the statistical nature of pair production, this contribution to the fluctuations is proportional to the square root of the number of electron–hole pairs created, i.e. of the energy loss. The total width of a peak in the X-ray spectrum is then given by an expression such as Equation (15),

\[
\Delta E = \sqrt{A + BE_X}
\]

where \(A\) is the square of the electronic noise contribution, \(B\) is the square of the so-called Fano-factor relating fluctuations to the square root of energy loss, and \(E_X\) is the X-ray energy corresponding to the peak. This behavior of \(\Delta E\) versus X-ray energy is taken into account when deconvoluting complex spectra.

However, the actual spectral line shape may be more complicated than Gaussian if ballistic deficit and/or pulse pile-up effects are present. Even in the absence of these effects, for high precision deconvolution an accurate representation of the detector’s response is needed. Even minor effects give rise to lineshape distortions, which have to be taken into account, in particular to properly detect and quantify small peaks on the tails of larger ones. Figure 13 illustrates the main contributions to the lineshape. Several deviations from the ideal Gaussian shape can occur to a larger or smaller extent depending on the specific detector.\(^25\)

A major effect that must be mentioned is the presence of an additional satellite peak – an escape peak – at an energy lower by 1.74 keV than the full energy peak.
which may be important to an evaluation are: mistakes between an escape peak and a full-energy peak not properly taken into account. Examples of possible rise to some confusion in the spectra deconvolution if overlap the full-energy peaks of other elements, giving and intensity of the escape peaks because they may 10 keV. It is important to keep in mind the presence peak falls from about 1% at 5 keV to about 0.1% at relative intensity of the Si escape peak to the full-energy deconvolution. The resulting K-series X-rays of silicon (1.74 keV) may then escape the detector before releasing their energy to the crystal. In these cases, the total energy released to the crystal is 1.74 keV below the primary X-ray energy. The relative intensity of the escape peak with respect to the corresponding full-energy peak increases with decreasing X-ray energy. This is because the average depth of interaction of the primary X-ray from the detector surface is lower at lower X-ray energies, and it is then less probable that the silicon X-rays produced by fluorescence are recaptured within the crystal. The relative intensity of the Si escape peak to the full-energy peak falls from about 1% at 5 keV to about 0.1% at 10 keV. It is important to keep in mind the presence and intensity of the escape peaks because they may overlap the full-energy peaks of other elements, giving rise to some confusion in the spectra deconvolution if not properly taken into account. Examples of possible mistakes between an escape peak and a full-energy peak which may be important to an evaluation are:

- Ca Kα escape (3.69 – 1.74 = 1.95 keV) with the P Kα line (2.00 keV)
- Cr Kα escape (5.41 – 1.74 = 3.67 keV) with the Ca Kα line (3.69 keV)
- Fe Kβ escape (7.05 – 1.74 = 5.31 keV) with the Cr Kα line (5.41 keV).

2.6.3 Optimization of Detection Limits over a Wide Range of Z

As discussed in section 2.2.1 (Figures 7 and 8), the physics of X-ray production in PIXE unbalances the detection efficiency in favor of the low- and medium-Z elements. This holds true even after using the favorable circumstance that L-series rather than K-series X-rays can be used for the quantification of higher-Z elements. This unbalance is a problem when detection of low or trace quantities of high-Z elements is required in the presence of a lower-Z matrix. Figure 7 shows that, if the count rate due to the low-energy X-rays emitted by low-Z elements is kept within tolerable limits, the total number of counts of X-rays from medium- and high-Z elements is too small within reasonable measurement times. In this situation two strategies may be adopted. The first uses two X-ray detectors simultaneously, which complement each other in terms of the efficiency curve and the solid angle covered. One detector is chosen to cover the widest possible solid angle (which increases efficiency regardless of the X-ray energy), but is prevented from obtaining a large count rate from low-energy X-rays by shielding its surface with an absorber of appropriate thickness (this reduces the efficiency for just the low-energy X-rays). This detector is thus optimized for the medium- and high-Z elements but, due to the absorber, it is practically blind to the lightest elements (see the efficiency curve in Figure 8). The second detector, with no absorber but covering a much smaller solid angle, is then used to simultaneously provide analytical information concerning the low-Z elements. This case is represented by the efficiency curve of Figure 7. The combined effect of the two-detector system, when both L- and K-series lines are used, is that a much broader range of Z is covered with more homogeneity in the detection efficiency.

By changing the absorber on the higher-Z detector and the solid angle of the lower-Z detector (by using appropriate collimators), it is possible to optimize the global detection efficiency over the two detectors to the widest range of Z, tailored to the particular analytical problem (which trace elements are of interest, the matrix composition, etc.). A cheaper alternative to a two-detector system is the use of a so-called funny filter on just one detector. A funny filter is a nonhomogeneous absorber, which can be constructed from a stack of foils having central apertures of different sizes. In this way different absorptions can be achieved for different solid angles. Thus the detection efficiency for higher-energy X-rays (which are little or not at all affected by the presence of the absorption layers) can be actually made larger than for the lower energies. In other terms, referring to Equation (7), the parameter Ω becomes an increasing function of X-ray energy, getting higher for higher-Z elements. A judicious choice of the funny filter geometry and composition can compensate effectively for the drop in X-ray production cross-section at higher Z. The drawback is that the actual shape of the function η versus E becomes more irregular than with a homogeneous absorber (or no

![Figure 13](image-url) Diagram of the different lineshape components for a Si(Li) detector in response to an X-ray. (Reproduced by permission from Campbell.28)
PIXE (PARTICLE-INDUCED X-RAY EMISSION)

This results in a more difficult modeling of the efficiency curve \( \eta(E_X) \), which in turn is essential to obtain accurate quantitative results with PIXE. In practice, when using a funny filter a large number of standard reference samples (one for each element over a much larger \( Z \) range) is needed to experimentally determine the detailed behavior of \( \eta(E_X) \). Even so, the uncertainty remains larger because the impact of possible inaccuracies in the knowledge of the areal densities of the individual standards is no more attenuated by the effect of “averaging” with neighboring-\( Z \) standards that is instead allowed when in the presence of a smooth behavior with \( Z \).

2.7 Micro-PIXE

Depending on the specific analytical problem, one may need a relatively large size of probing proton beam (up to tens of square millimeters, when it is necessary to get an average composition on a wide surface), or a very small one (when the surface distribution of the elemental concentrations has to be mapped with the highest possible detail). When the beam diameter is reduced to about 100 \( \mu \text{m} \) or less, one generally talks about microbeams. In the simplest microbeam set-ups, the cross-section of the beam on the target is defined by collimation, by placing slits or apertures upstream, not far from the target. By this procedure, beam sizes as small as 100–200 \( \mu \text{m} \) can be obtained; this represents a sufficiently small size for many applications requiring detailed information on spatial distribution of elemental concentrations.

Sometimes an even smaller beam cross-section is necessary, and any further reduction of the beam size by brute collimation is no longer effective. At very small apertures, scattering of the particles by the slit or collimator edges produces significant beam halos over an area larger than that geometrically defined by the aperture. To obtain beam sizes down to 1 \( \mu \text{m} \) or below, strong focusing is necessary. The production of well-defined and sufficiently intense beams (1 nA of proton current is not exceptional) of the order of 1 \( \mu \text{m} \) is now a standard feature of set-ups based on strong focusing and the technical aspects of these set-ups have been widely reviewed.\(^{29–31}\) Essentially, a microbeam is obtained through a beam-optics system which includes an object (a small, micrometrically adjustable slit aperture illuminated by the beam from the accelerator) and a set (doublet, triplet or quadruplet) of magnetic quadrupoles acting as a whole on the particle beam as a positive lens. The beam is focused on the target (image of the system), the distance of which from the quadrupoles is much smaller than the object–lens distance. In this way, high demagnification is obtained. In order to reduce the geometrical aberrations, the beam divergence at the entrance of the quadrupole system is strongly limited by collimator slits (Figure 14).

Almost invariably, the microbeam facility includes a system to fast scan the beam two-dimensionally over the sample, with a raster area having sides of the order of up to several hundred micrometers. This is accomplished by magnetic deflection with coils prior to the quadrupole focusing. Figure 15 is a photograph of the final section of a proton microprobe, including collimator slits, scanning coils, triplet of magnetic quadrupoles and irradiation camera, with micrometric adjustment of the target position and viewing microscope from outside.

In the presence of scanning coils, data acquisition is performed in the so-called list-mode. This means that when an X-ray is detected, a triplet of data is stored: the X-ray energy and the two coordinates of the beam spot position at the detection instant (deduced by the current values of the scanning coils at the instant of X-ray detection). The analysis of the triplets, which can be performed on line, includes the possibility of obtaining elemental maps (plotted as the number of detected X-rays of any given energy as a function of position over the whole scanned area). Alternatively, it is possible to
NUCLEAR METHODS

reconstruct the X-ray spectrum detected over any portion of the scanned area (down to pixels that correspond to the limits of lateral resolution, i.e. to 1 µm or even less). This is similar to the result of EPMA; however, the better MDLs offered by PIXE (section 1.3.1) make it possible to extend elemental mapping even to trace elements.

When pushing the limits of lateral resolution to their extremes, a number of factors come into play which limit the possibilities of obtaining ever smaller beam spot sizes. First, the complex aberration effects of the probe-forming lens system have to be diagnosed and minimized. These include:

- astigmatism, due to the lack of cylindrical symmetry of the quadrupoles;
- higher-order multipole contamination of the quadrupole field, deriving from inaccuracies of construction of the quadrupoles (deviations from fourfold symmetry);
- spherical aberrations, coming into play only if higher currents are needed, which implies the acceptance of a larger beam divergence;
- rotational, translational and tilt misalignments of the quadrupole multiplet assembly.

Second, external sources can also produce broadening of the beam spot. Among these, an important role is played by the accelerator characteristics:

- beam brightness at the object slits, which in turn depends on many factors connected with the ion source, accelerator, and up-stream beam optics design;
- accelerator energy instabilities, which produce the equivalent of chromatic aberrations.

Other relevant factors affecting the quality of the microbeam are:

- scattering phenomena, both at the slits and due to residual gas in the beam line due to poor pumping;
- stray electromagnetic fields that may be caused by several sources in the vicinity of the beam line (transformers, motors, power supplies, etc.);
- mechanical effects such as vibrations (e.g. induced by pumps) in the target area, or even slow drifts of the target during irradiations, such as those caused by thermal effects.

One final point concerning PIXE with proton microbeam set-ups is that although a lateral resolution as small as 1 µm or less can be obtained, one should not forget that the depth investigated by PIXE at standard bombarding energies (2–3 MeV) is up to some tens of micrometers (sections 1.3 and 2.2). Consequently, in thick targets the compositional information is an averaged value over a larger size. Thus full advantage of ultrahigh lateral resolution is only obtained with very thin targets (such as with certain biological specimens), or in samples where the elemental map of the surface layer is also representative of the structure in depth (as in the analysis of electronic devices).

3 SURVEY OF THE MAIN ANALYTICAL APPLICATIONS

The analytical applications of PIXE are innumerable. Regular international conferences are held to give scientists of the IBA community the opportunity to exchange ideas on the technical developments of PIXE (improved databases of fundamental parameters, detection systems, data reduction codes, etc.), and on new analytical applications. New ideas continue to be proposed, especially when PIXE is combined with other IBA and nonIBA techniques, which is performed more and more. The following discussions outline some general considerations concerning groups of applications, with no claim to being exhaustive. The intention is to point out the peculiar analytical aspects of PIXE that are specifically important in each of the main applications.

3.1 Environmental Pollution Studies

These applications were among the first to be successfully performed during the early years of PIXE development. Both water pollution and air pollution are currently investigated, with more emphasis on the latter. The importance of aerosol analysis is obvious, both in view of air quality assessment in urban and industrial areas (impact on the health of humans, animals and plants), and as a tool in the investigation of general atmospheric phenomena such as short- and long-distance air transportation, visibility, and climate.

Since the early stages of aerosol investigations by PIXE, several reasons for a widespread use of this technique became apparent.

- Variations in the atmospheric aerosol composition can take place over very short timescales (of the order of an hour) or on longer, seasonal, timescales. The same applies to spatial variations: air transportation and deposition phenomena can produce extremely different results depending on the site of measurement. This large variability calls for vast numbers of analyses, and a method such as PIXE, capable of yielding fast quantitative results, lends itself to these
investigations much better than does conventional chemical analysis.

- All elements are potentially important in aerosol analysis, because many can be toxic, and because any compound, bound in particles of the appropriate size, can have an effect on visibility (by the scattering of light). Also, the simultaneous detection of groups of elements, occurring in particular ratios, can be a signature of the source of pollution. Their detection at different sites may constitute an important indicator of long-range air transportation phenomena. In performing the necessary multi-element quantitative analyses, the PIXE method offers advantages in terms of time and cost, with respect to chemical methods or optical spectroscopies. Particularly important is the possibility of complementing PIXE with the simultaneous use of other IBA techniques to extend the range of detectable elements, especially the lighter ones.

- The total quantity of aerosol mass available for compositional analysis is quite small. Typical aerosol mass concentrations in air range from a few to over one hundred micrograms per cubic meter. Traditional ways of collecting aerosol are by filtration over long periods of time, using large pumps and large-size filters in order to collect at least one or two milligrams of aerosol for the analysis of only some elements or compounds. The sensitivity of PIXE, for which overall quantities of about a microgram are adequate for a multi-element analysis, considerably reduces collection times and makes the use of much smaller pumping set-ups possible.

- It is important to obtain separate information on the composition of aerosols of different sizes. The particle size distribution is not homogeneous, and the relevance of particles of different sizes is quite different. As far as the impact on health is concerned, this is clearly connected to the penetration of particles into the breathing apparatus, with smaller ones reaching deeper levels and therefore being potentially more dangerous. As to visibility problems created by aerosols, the size-dependence of their effect, being connected to the scattering of light, is even more obvious. Finally, the size distribution also provides information on the sources of pollution. For all these reasons, sampling methodologies providing size-fractionation of the aerosol are highly desirable. These have been developed using inertial impactors that exploit the differing inertias of different sized particles when following air flow paths in special collectors. These samplers may also provide time-sequence deposition of the size-fractionated aerosol on streaks (typically, about 1 cm high) whose total length may correspond up to 1 week of aerosol collection or even more; each section of about 1 mm width corresponds to a short sampling period of typically 1 h. PIXE can be used to analyze these sections selectively, thereby reconstructing the time behavior of the aerosol composition. The overall quantity of aerosol deposited on each section is minute, typically of the order of 10 µg. The high absolute sensitivity of PIXE is therefore exploited to the highest degree. No other technique enables the analyst to obtain such a high time-resolution of the variation in aerosol composition, with simultaneous sensitive detection of a very large number of elements in runs lasting a few minutes. In addition, after PIXE measurements the samples remain available for alternative analyses, to corroborate or complement the data obtained by PIXE.

- The analysis of aerosol collected on “traditional” filters is also important. Daily sampling with these filters is routinely performed by public authorities in many western cities, but in most cases the only parameter measured is the total mass of aerosol deposited over the day. The collected aerosol is analyzed compositionally only for specific campaigns aimed at obtaining information about a few specific components; in these cases, with traditional analysis, the samples are destroyed. The nondestructive PIXE analysis of time sequences of these filters allows instead the trend of air pollution to be followed over long timescales without losing them for further tests. The reconstruction of aerosol composition has been reported in urban environments for periods of months or years. It is obvious that over these timescales the use of 1-h resolution streakers would result in unmanageable quantities of data. Also with traditional filtering procedures, therefore, PIXE provides a precious tool in both widening the range of elements detected from each filter and preserving the samples for further investigation.

Let us now summarize the typical procedure for a PIXE analysis of aerosols.

After sampling on streak (for high time-resolution analysis), or on one-day filters (for studies of trends over long timescales), proton irradiation is performed with runs typically lasting a few minutes per sample.

For the analysis of streaks, the “sample” is each section of the streak and use is made of relatively small-size beams (typically 1 mm; microbeams are not needed). After completion of a run, the next section is immediately exposed to the beam by simply shifting the streaker by the proper distance, often in an automated process. For the daily filters, larger beams (made homogeneous over their cross-section by one of the methods outlined at the
end of section 2.4.1) are used and/or scans are performed over the whole area.

The currents used are typically 5–40 nA. Both in-vacuum and external beams have been used for this kind of measurement. External beams are preferable both to facilitate positioning, changing and/or scanning of the samples, and to minimize the risk of selective loss of some aerosol components when under the beam.

The spectra are normalized to the integrated beam charge on a Faraday cup behind the sample (the aerosol deposit plus substrate are thin enough to let the beam pass through), or to alternative normalization parameters (section 2.4.3).

The deduction of areal densities of the different elements on the deposit is then performed by simple comparison with thin standards. In the thin-target approximation, only the very lowest-Z detected elements may be slightly underestimated, due to the onset of self-absorption effects (section 2.2.2) within the particle grains. The latter effects can be of some relevance (up to 50%) only for the larger-size fraction of the particulate and for elements from Na to Si. However corrections can be applied, and/or these elements may be simultaneously detected by alternative IBA techniques, such as particle-induced gamma ray emission (PIGE), which also may produce data on lower-Z elements undetected by PIXE, such as fluorine.

The elemental concentration in the air is finally obtained through knowledge of the sampling parameters (area of pumping aperture, flow rate, duration of sampling).

In a typical collection campaign, the amount of data accumulated is huge (30–40 elemental concentrations from each sample, separation according to particle size, hundreds of streaker sections (or daily filters) analyzed). Therefore, a statistical analysis must be performed. Principal component analysis (PCA) or factor analysis (FA) are routinely performed on the data sets. These processes group the detected elements into factors according to the similarity of the behavior over time of their concentrations, thereby indicating pollution sources, reconstructing their relative weights in the total particulate mass, and also disentangling possible contributions from different sources to the same element.

Owing to the large amount of data that can be collected in a relatively easy way, large-scale monitoring of environmental quality makes wide use of PIXE data. For instance, the US monitoring network “IMPROVE” is largely based on PIXE-determined elemental concentrations in air.

Hundreds of papers have been published on PIXE measurements of aerosols. Specific results and review articles are published on the occasions of the triennial International PIXE Conferences. Several reviews are available.

### 3.2 Biomedical Applications

Biomedical applications of PIXE have been reviewed in detail together with exhaustive lists of references. Also for biomedical work, a large number of specific papers are published in the Proceedings of the International PIXE Conferences, Nuclear Microprobe Conferences, and the more recent topical series of bio-PXConferences.

The main reason for the great success of PIXE in biomedical applications is linked to the very nature of biological materials, where light elements – undetected by PIXE – are the dominant component. This favors attaining the best results in terms of MDLs for higher-Z elements. Provided that the samples can tolerate the relatively intense beam currents, MDLs well below the ppm level are easily reached. This trace element capability makes it possible to obtain precious information on physiological and pathological processes in biomedicine, where the oligo-elements often play a key role. The problem is in the correct preparation of the samples, because the biological matrix is easily damaged by irradiation and elements such as hydrogen and oxygen may be lost to a large extent due to heating. However, when these problems are adequately tackled, biomedical applications of PIXE can yield important results.

The second feature of PIXE that is important in biomedical applications is the high spatial resolution, i.e. the possibility of mapping trace element distributions in the tissues with a high definition. If a microbeam is used, the intracellular distribution of trace elements may be revealed.

To obtain good results in biomedical PIXE applications, close interdisciplinary collaboration between physicists and biologists is important at all stages of the experiment. This includes experiment design, sample preparation, data collection and processing, and interpretation of the results.

Traditionally, applications of PIXE in biomedicine have focused on the detection of trace quantities of transition elements and heavier elements in tissues. More recently, interest has shifted to the detection of lighter elements, such as aluminum, potassium and calcium. Often, the low concentration levels of these elements, which are well within the analytical capabilities of PIXE, are not easy to detect with alternative techniques, especially when dealing with small tissue samples or at the cellular level.

The sampling strategy is crucial to obtaining significant biodata from any analytical technique and must be adapted to the specific features of the chosen methodology. An essential point to bear in mind is that a large number of samples is necessary because of the large variability of trace element concentrations in biological
tissues. In this respect, PIXE is a good choice because it can analyze large numbers of samples in a relatively short time, in addition to preserving them for further complementary analysis. The latter point is an advantage in biomedical investigations because the bio-availability of trace elements may be quite different, depending on the chemical form in which the elements are bound. Thus further analysis of the same sample can be performed to yield this essential chemical bonding information.

Bio-PIXE experiments are usually performed on samples collected from living matter (biopsies). To avoid or minimize ethical problems connected with the acquiring of such samples, many investigations are performed on dermatological samples, such as nails or hair, as biological indicators of a physiological or pathological state of the individuals from which they were taken. The use of body fluids, such as sweat, tears, urine or blood, also implies minimum invasion in the sampling procedure. In any case, even when dealing with biopsies, the high absolute sensitivity of PIXE, requiring the collection of only minute amounts of tissue, is a good reason for selecting this technique. However, due to the very small amounts of sampled material involved, special care must be taken to avoid contamination from the surgical instruments used for the biopsies.

The need for small amounts of sampled material is beneficial to studies aimed at clarifying the processes of forest decline. Drill cores are collected from trees, small enough as not to harm them, and the radial trend of contaminant elements from environmental agents studied along the tree rings. One exploits here the fact that, in plants, only the external layer is living matter, interacting with the environment, and that each annual tree ring records the elemental content resulting from equilibrium with the environment for the corresponding year. Past environmental conditions can be thus reconstructed by simple PIXE scans on the small samples collected.

Sample preparation for bio-PIXE analysis depends on whether macro-analysis or micro-analysis is intended. In macro-analysis, the desired spatial resolution in the detected elemental concentration is no smaller than a fraction of a millimeter; sometimes an average over a larger dimension is required. When this is the case, many biological materials can be analyzed with a minimum of preparation, especially when an external beam set-up is used. Examples of materials analyzed in this way are botanical samples such as leaves, wood, and tree rings, or animal (or human) specimens such as bones, nails, hair, and teeth. Direct beam bombardment is possible in these cases, but no internal standard can be included and the absolute quantitative analysis may be difficult with PIXE alone because the matrix material is to a large extent undetected. However, in these studies it is often the relative behavior of minor or trace element concentrations that is searched for, so the matrix composition can be unimportant. Another point to be kept in mind when extracting analytical information from these untreated thick samples is that the total quantity of interrogated material volume is small, in the milligram range, due to the essentially surface character of PIXE analysis (section 2.2.2). Caution must be used in evaluating the representativeness of the results, which may be questioned if the material is not homogeneous to the macroscopic scale. Finally, surface roughness can also cause inaccuracies in the quantitative data, especially as far as lower-Z elements are concerned.

Soft tissues are often dried before analysis. The technique of lyophilization by freeze-drying is most common and performed by commercially available equipment. It has been shown that, for macro-analysis, the original composition is not affected by this procedure (whereas the spatial distribution of elements in micro-analysis could be affected if crystals are formed or thawing occurs). After drying, the tissues may be pulverized, homogenized and compressed to pellets for analysis. In this process, the material can be mixed with ultra-pure carbon powder, to ensure that the sample is electrically conductive. This avoids problems connected with insulated samples during bombardment. Throughout all these steps, great care must be taken to avoid contamination, such as from the pressing surfaces of the pelletizer.

To further increase sensitivity to the trace elements, the organic matrix mass can be reduced by well-established techniques such as wet ashing, dry ashing, low-temperature ashing, and acid digestion. The possible selective loss of some elements (e.g. chlorine and bromine in dry ashing) must be considered with care.

The preparation of biological samples for micro-PIXE analysis is different. It is clear that, for the result to be significant in terms of biological information about trace element distribution at the cellular or sub-cellular level, the spatial structure must be preserved during sample preparation and irradiation. Experience gained in the preparation of samples for electron microscopy is not only of partial help here, because in those preparations chemicals are often added to increase visual contrast, and these may contaminate or selectively remove certain elements. Cryo-preparation techniques have been developed instead that lead to almost instantaneous freezing of the cells with preservation of a life-like state in terms of the elemental distribution. The frozen material must then be maintained at low temperature (below 130°C) and the analysis performed on thin sections obtained with an ultracryomicrotome. As these sections show very little image contrast in using optical microscopy, their positioning under the microbeam with traditional optical methods is difficult. Contrast enhancement by
the integration interval, discussed in section 2.2.2, are concentrations from the PIXE spectra can be as accurate. This comparison is useful in that it adds reliability to the minor elements, the differences in the probed depth and techniques with high spatial resolution, such as mass spectrometries SIMS (secondary ion mass spectroscopy) or LAMS (laser ablation mass spectroscopy). With this precaution, both techniques can be used on the very same sample. In addition to providing additional information on trace elements, PIXE also provides quantification of the major and minor elements so that the results can be compared to EPMA data for the latter elements. What is crucially important is that the additional trace-element analysis provided by PIXE is achieved in a nondestructive manner, unlike alternative highly sensitive techniques with high spatial resolution, such as mass spectrometries SIMS (secondary ion mass spectroscopy) or LAMS (laser ablation mass spectroscopy).

In comparing EMPA and PIXE results for major and minor elements, the differences in the probed depth and in spatial resolution (section 1.3.1) must be considered. This comparison is useful in that it adds reliability to the overall analytical data. The quantification of elemental concentrations from the PIXE spectra can be as accurate as 1–2%, for two reasons. First, the sample thickness is infinite and the problems connected with knowledge of the integration interval, discussed in section 2.2.2, are avoided. Second, the undetected fraction (very light elements) is in most cases (such as for silicate rocks) easy to estimate just on the basis of the detected fraction; or even all elements are actually detected, as in sulfide rocks. In silicate rocks the elements can be considered to be present in the form of oxides, thus the only undetected element is oxygen and its abundance can be estimated from the stoichiometric ratios to the detected elements. In practice, an initial estimate is done of the total oxygen abundance (which is often around 40%), in order to make a first approximation of the matrix effects in the computations described in section 2.2.2. Iterative procedures then lead to a self-consistent dataset of all elemental abundances, oxygen included.

Typical problems that have been addressed by microPIXE in the field of earth sciences are trace element partitioning between phases, which provides important clues to the physical and chemical parameters of the environment at the time of rock formation, and mineral zoning effects as regards trace elements. The latter frequently do not follow the pattern of major elements, and the different behavior is of relevance to geologists. These investigations require a beam of small dimensions; however, this does not necessarily imply the use of a microbeam. Beam sizes of a few tens of microns may often be adequate. One should keep in mind that the depth within the mineral, interrogated by the proton beam, is of the order of 10 µm, or more for the medium-to-heavy elements typically searched for in trace quantities. A higher lateral resolution would therefore bring no benefit (section 2.7). The relatively broad size of microbeam required means that no specially refined tuning is needed on the set-up.

More traditional, broader beam sizes have been used to investigate rocks to obtain bulk composition data. Here, the obvious competitor to PIXE is XRF which, when operating on a larger spatial scale, is capable of yielding trace element abundance. Indeed, the same kind of problems are addressed by XRF and PIXE, and even the same samples can be used. As the problem in bulk composition analysis is the inhomogeneous structure of the rocks, the latter have to be thoroughly ground to a very fine powder and homogenized. The final sample preparation step is usually pressing the material into pellets, which are then exposed to the X-ray or proton beam. Due to the trace element capability of both techniques, great care must be taken to avoid contamination by the instruments used for grinding and pressing. Although in principle both XRF and PIXE are capable of yielding global information on composition, it must be said that the former technique has better MDLs, if properly applied, for the higher-Z elements, whereas PIXE is better for the lighter ones. Another difference lies in the different depth investigated, but
this is not relevant for homogenized samples because the pellets are effectively infinitely thick for both techniques. Finally, a common feature of XRF and PIXE analyses, which is disappointing to geologists, is that the important problem of rare earth patterns cannot be investigated. On the one hand, the detection efficiency for the K-lines of rare earth elements (which are sufficiently energy separated from each other) is too low, so that they cannot be detected at their low levels of concentrations. On the other hand, the L-series X-rays, which might instead be detected with more efficiency, cannot be safely deconvoluted because the overlaps of their multiplets are too close. Some work has been done to overcome these problems. Higher-energy PIXE has been attempted, but the advantage of the increase in K-series X-ray production cross-sections is accompanied by a much higher continuous background, induced in the spectra by the onset of many nuclear reactions. The latter lead to emission of gamma rays, producing Compton interactions in the detector (section 3.1). Also the attempt for a proper deconvolution of the close-lying multiplets of L-series X-rays was basically unsuccessful, as even small differences in the assumed X-ray lineshape in the spectrum fitting procedure alter the deduced relative intensities of the various elements.

When considering broad-beam PIXE applications in the earth sciences, not only XRF but all the other traditional techniques can usually be applied as well. This is because there is usually plenty of material to analyze and the nondestructive character of XRF and PIXE becomes less important. The advantage of XRF and PIXE is in their multi-element capability, which makes the compositional characterization of samples from bulk materials much faster. However, as a summary consideration one should admit that the real benefit of PIXE to the earth sciences is only when using microbeams for trace-element distribution studies.

3.4 Applications to Art and Archaeology

Recent surveys of PIXE applications in the field of art and archaeology can be found. These applications probably started later than those mentioned above, but have now been developed to a large extent as a result of more widespread use of external beam set-ups. The importance of PIXE measurements (and IBA in general) in this domain is demonstrated by the installation of a dedicated accelerator in the Laboratoire de Recherche des Musées de France, in the basements of the buildings of the Louvre Museum in Paris. With the prominent use of PIXE analyses among others, this accelerator has produced significant contributions to a better understanding of the materials and techniques used in the past for the production of works of art. Intense and significant activity in this field has also been performed in many other laboratories throughout the world.

The problems addressed by PIXE analysis in this field fall into two categories: first, an advancement of the knowledge of materials and production technologies used in works of art in ancient times; second, the investigation of materials prior to restorations, so as to appropriately choose the restoring procedure, and avoid incompatibilities and irreversible effects between materials.

The motivating forces within the first category can be many. Reconstructing the material composition of artifacts may lead to:

- deeper insight into the technical developments of the past, allowing the historian to better understand the advance in the technological skills of artisans at various sites and times;
- discovery of the sources of supply of raw materials, thus contributing to the solution of historical problems, such as the existence of certain trade routes at the time of manufacture of the ancient objects under analysis;
- indirect dating through compositional analogies with dated materials and, under favorable circumstances, lending support to attributions to specific artists, providing a criterion for authentication (or refutation).

To the second category of problems, namely the restoration of works, should be added the significant contribution to a better understanding of the deterioration of the works of art.

Whatever the reason for analyzing the material of an object of artistic or archaeological relevance, in almost all cases a mandatory requirement is that no damage must occur, and quite often the physical removal of some material for analysis is forbidden. This raises a difficulty in that the inherent inhomogeneity of the materials used to produce works of art (whether one is dealing with paints, or metal alloys, or terracotta, or any other) calls for an analysis extended to many samples. The representativeness of the results might be otherwise questioned. Hence there is a need to perform such analyses with techniques capable of yielding a full compositional characterization of artifacts in a fast and nondestructive way. PIXE meets these requirements probably better than any other analytical technique. With the exception of metal objects, external set-ups are needed so that the nondamaging character of the technique is thus fully preserved provided that sufficiently low beam currents are used. Low beam intensities, on the other hand, are feasible in most investigations because of the nonthin targets (i.e. the quantity of material is relatively large) and because the problem is often not the
search for trace elements. Typical beam currents used in this kind of application are well below 1 nA, sometimes down to a few picoamps.

In terms of risks of damage, the most sensitive precious materials are glass, porcelains, and any vitrified surface. With these materials, even with external beams, currents of a few tens of picoamps can sometimes produce a visible stain after a measurement. This sort of damage can often be tolerated, but the curator of the object must be warned about the risk. This damage is attributed to atomic dislocations in the structure of the material, giving rise to color centres. Stains induced in this manner have been often reported to fade away after some days or weeks, due to a self-annealing process, even at room temperature. To minimize the effect, whenever the sample size makes it possible, a diffused beam over a larger area may be employed, or a smaller-size beam may be scanned across the surface (or the surface moved under the beam).

Although all kinds of materials may be analyzed by PIXE, most published work has concentrated on gold artifacts (coins, jewels), temperas used in miniatures in illuminated manuscripts or incunabula, and terracotta. Relatively little PIXE activity has concerned the materials of traditional paint on wood or canvas. This is because PIXE is a surface analysis technique, and little or nothing can be discovered about the deeper layers. Thus, if PIXE is performed on the paintings as they are, the protective varnish, which is invariably laid over the color in paintings on wood or canvas, prevents access to the paint materials. Material sampling is seldom allowed; alternatively, the varnish could be removed, but this is only done on the occasion of restorations, and is not normally permitted for general investigations, such as when trying to characterize the color palette of a given painter or school.

For paints, the field where PIXE is best exploited is that of illuminated ancient books. Here, no varnish was used because the paints were believed to be naturally protected by remaining unexposed to direct light and atmospheric agents for most of the time. Much PIXE work has concentrated on this subject, and unexpected results of art-historical importance have been found; for instance, the widespread use of ultramarine blue has been detected in Italian scriptoria dating from early medieval times. Until this finding it was believed that the pigment (obtained by a sophisticated refining technique from lapislazuli, a semiprecious stone only found in Afghanistan) was reserved for very important works, at least until the early Renaissance, because of the high cost of import from a distant site.

All PIXE work on miniature paintings has been performed with external beam set-ups. This is essential with manuscripts, because of handling considerations and because only by the use of an external beam (in a helium flow) can the measurements be really nondamaging, in all senses.

The surface character of PIXE analysis also explains why most of the published work on metal products concerns gold. The surface patina layer covering ancient objects made of other metals is a problem to PIXE, unless the material under study is the patina itself (which can in fact be the case sometimes). As far as gold items are important work includes that by Demortier, which led among other things to the discovery of skillful soldering techniques as early as 3000 years ago. This work demonstrated the use of various gold alloys with decreasing melting temperatures, which avoided the unsoldering of nearby previously soldered details. These measurements have been performed both with external beams and with in-vacuum microbeams. For this kind of object, indeed, no disadvantage (damage, or difficult handling due to large size) comes from the use of a vacuum set-up, whereas the use of an in-vacuum microbeam provides sometimes a better tool of analysis.

Terracotta has been often investigated by PIXE analysis. The information searched for in this case is usually a provenance clue, often based on the trace-element content of the material. Thus, the PIXE quality most exploited is its very low MDLs. When dealing with terracotta, the compositional analysis is usually performed on fragments, whose esthetical value is irrelevant; therefore, higher beam currents may be used with no fear of possible visible damage, and the sensitivity to trace elements achieved in runs lasting a few minutes. However, due to the surface character of PIXE analysis, caution must be exercised when deriving conclusions from the detection of traces – surface contamination might be the reason for finding trace concentrations of unexpected elements. These risks must be carefully evaluated and procedures for reducing them adopted (such as analysis of cleaved surfaces of the fragments, or preliminary cleaning with appropriate noncontaminant processes). The statistical analysis of detected trace-element abundances over large series of samples may also help in discriminating significant results from accidental findings. An alternative to direct irradiation is to sample some material, which in small amounts is often allowed when dealing with fragments. In these cases, the material can be powdered and pressed into pellets for analysis. The same considerations as for the analysis of rocks with macro-PIXE (section 3.3) apply in this respect, in particular about the alternatives to PIXE for these analyses.

An example of extensive PIXE investigations of this kind is the analysis of pottery and obsidian artifacts performed in Australia. A large number of pottery samples have been analyzed with a PIXE/PIGE set-up; their composition was clearly correlated to local
sources of clay, which made it possible to establish relationships between prehistoric settlements and their trade connections. The obsidian artifacts, which were largely used by prehistoric populations as tools for everyday life or for hunting, were prepared using material collected from local deposits of volcanic origin. The compositional characterization of hundreds of these tools by PIXE and PIGE, followed by statistical analysis for pattern recognition, made clear separations into different groups possible. Because the populations took their tools with them when migrating from one land to another (even over distances of thousands of kilometers), the archaeologists were able to reconstruct the processes of migration by matching the composition of obsidian tools to that of volcanic flows in quite different places.

3.5 Applications to Historical Problems

Although related to the previous section, the studies described below have been separated out because, for them, the use of PIXE has been particularly useful and in certain respects unique. The study of ancient written documents, namely of the composition of paper, parchment, and especially ink, is a tool to characterize and differentiate them. Such characterizations address problems of chronology, authenticity, or technical procedures for the production of books in ancient times. For the study of inks in particular, PIXE is an exceptionally suited tool owing to its high absolute sensitivity, its nondestructivity, the possibility of using beams well below 1 mm in diameter in external set-ups and to perform simultaneous quantitative analysis of many elements. All these features make it really useful for these problems.

In a study of one exemplar of the Gutenberg Bible, the paper and ink were analyzed by an external 1-mm² beam. The ink was notable for its high Cu and Pb content, and their weight ratio was used to characterize the ink. It was thus possible to reconstruct the sequence of printing of the various pages of the book.

Another study of the same group concerned the so-called Vinland map, which is believed to be a pre-Columbus document giving the first cartographic evidence of North America. However, its authenticity had been debated and after a chemical analysis (which was performed on a forcedly limited number of tiny samples of ink, as they had to be picked up from the map), it was concluded that it must be a forgery because of a high content of TiO₂, which has become available only in recent times. An extensive PIXE analysis of ink from this document, performed instead on a very large number of spots, with no need for picking up material and no damage, showed that the amount of titanium was in fact quite small, thus re-opening the possibility that the map is authentic. In this case, the nondestructive character of a PIXE analysis in situ was the winning card.

Ink analysis by PIXE has also been used to indirectly reconstruct the chronology of documents, as in the following example. During his life Galileo produced, besides the published works, hundreds of notes, handwritten on loose sheets of paper, where he wrote propositions and sketched diagrams about his ideas on the problems of motion and on astronomy. These sheets are obviously undated and conflicting opinions have been raised within the community of science historians about their chronological order. Establishing their dates on the basis of an objective criterion is important for the reconstruction of the development of Galilean thought. Analysis with PIXE of the ink composition in some of Galileo’s dated hand-written documents — such as letters — first showed that a correlation can be established between different ink compositions and periods of Galileo’s life. The inks are of the so-called metallgo-gallic type and the quantitative ratios between the various metallic components (Fe, Ni, Cu, Zn, Pb) vary from one manuscript to another, so that they can be used to characterize different periods. The idea is then to characterize the ink of the undated propositions in the loose sheets, and attribute them to the different periods on the basis of composition matches to the dated documents. Even when an absolute date cannot be established, an important objective is a relative dating, i.e. differentiation between the inks of the various undated documents. Indeed, most of the controversies concerned whether certain notes had been written at the same or at different times. Using these criteria, both absolute and relative dating have been possible for a number of these loose sheets and controversies between historians of science have been solved.

It is important to keep in mind that this contribution is to be considered in the frame of a global approach where the historical and textual evidence is of course of primary importance. This calls for the need for integrated teams of researchers from the various fields to work together throughout all the phases of the investigation.

From a technical point of view, PIXE analysis of the inks in documents is easily performed with external beams. The typical beam size used is between 200µm and 1 mm, with no need for microbeam set-ups. Because the elements of interest are not trace elements in the inks, but are major or minor components, the beam currents may be kept very low (typically 100–200 pA) and no damage occurs. In extracting quantitative data, two circumstances must be considered. First, the beam will also excite X-rays from the paper (or parchment) substrate, so that the result refers to an effective target that is a combination of ink and substrate. This is taken into account by measurements on spots of uncovered substrate, and appropriate subtraction of the backing contribution, after beam charge normalization of the
ink plus substrate and substrate-only spectra. Second, the ink actually penetrates the substrate, to an extent depending on many factors such as substrate porosity, ink fluidity at the very instant of writing, and even ageing phenomena. These effects can lead to ambiguities in that the target thickness and the matrix composition of the effective target are to some extent uncertain. However, as far as the ratio of the elements of interest (medium or heavy metals) is concerned, it can be shown that the value deduced with no matrix correction is only weakly dependent on these parameters. Therefore, the accuracy of the thin target approximation (sections 2.2.1 and 2.2.2) remains sufficient for a meaningful ink discrimination (about 10% for the measured ratios). The differences between different inks are much larger than that, even with changes of orders of magnitude having been observed.

Prompt $\gamma$-neutron activation analysis (PGNAA) is a multielemental analytical technique based on the detection of $\gamma$-rays emitted by excited nuclei following neutron radioactive capture or neutron inelastic scattering. The accumulated count rate relative to the $\gamma$-ray energy characteristic of a certain isotope depends on its concentration. Measurements take place during sample irradiation. The technique can provide accurate information on the elemental composition of materials in a broad range of cases: raw materials, mineral exploration, contaminants, detection of forbidden products, such as drugs and explosives, inspection of containers and applications in health care. Among the main advantages of the PGNAA technique are: faster results; nondestructiveness; flexible sample requirements; bulk sample analysis; in situ application by direct on-line measurement; detectable unique signatures for most elements; improved accuracy for short-lived elements; low residual activity. On the other hand, the most significant limitations are: higher detection limits (DLs) as compared with delayed $\gamma$-neutron activation analysis (DGNAA); longer irradiation times; single (one-cycle) sample irradiation; impracticability of enhancing a specific isotope contribution by radiochemical or physical (half-life) separation techniques; requirement for relatively larger samples.

1 INTRODUCTION

PGNAA is a powerful analytical technique that can provide accurate information on the elemental composition of materials in a broad range of cases: raw materials, mineral exploration, contaminants, detection of forbidden products, such as drugs and explosives, inspection of containers (detection of plutonium) and applications in health care.

When a material is bombarded with neutrons, nuclear interactions in the sample may lead to the formation of excited compound nuclei that lose their excitation energy by the emission of one or more $\gamma$-rays (prompt $\gamma$-rays) and eventually one or more particles. PGNAA is based on the detection of the emitted $\gamma$-rays. The $\gamma$-ray energy identifies the element while the intensity of the line is a measure of the element concentration.

The analysis is the result of a combination of a number of different processes or steps:

- neutron emission by a neutron source (radioisotope, neutron generator, nuclear reactor, spallation source);
- neutron interaction with the sample’s constituent nuclei;
- emission of $\gamma$-rays following neutron capture or neutron inelastic scattering;
- $\gamma$-ray attenuation in the material;
detecting $\gamma$-rays (solid state or scintillation detector);

- conversion of detector counts in percent weight for the elements being analyzed based on a previous calibration of the system.

These steps and processes will be addressed in the following sections.

The PGNAA technique is best suited for measuring elements: (1) with very high neutron capture cross-section; (2) elements that decay too rapidly to be measured by conventional DGNAA; and (3) elements that through neutron reactions generate only stable isotopes or radioactive isotopes with a low probability of $\gamma$-decay.

The main advantages of PGNAA are: faster results; nondestructiveness (sample preparation is not needed); flexible sample requirements; bulk sample analysis (representative average for nonhomogeneous materials); in situ application by direct on-line measurement; detectable unique signatures for most elements; improved accuracy for short-lived elements; low residual sample activity.

On the other hand, the most significant handicaps are: higher DLs as compared with DGNAA, which restricts the number of elements that can be measured at trace concentrations; longer irradiation times; single (one-cycle) sample irradiation; impracticability of radiochemical or physical (half-life) separation to enhance specific isotope contributions; requirement for relatively larger samples.

The gauge response of a PGNAA analyzer is determined in a complex manner by the system parameters – geometry, source activity and neutron energy spectrum, and detector efficiency – and by certain properties of the analyzed sample such as bulk density and water content. It follows that the count rate caused by a given $\gamma$-ray line is a nonlinear function of the concentration of the element to be measured. There are, in principle, several methods for calibrating a PGNAA gauge. Experimental calibration methods use standards of known composition. An alternative method is the use of Monte Carlo codes to simulate the sample spectra and/or to establish calibration curves.

Trends in the evolution of PGNAA relate to both the instruments of the technique and the range of its applications.

The use of advanced neutron sources, improved spectrometers (Compton suppression and pair spectrometer), nuclear imaging techniques, sophisticated calibration methods and the extension of PGNAA to new materials and sample types are some of the trends which indicate that this technique has a promising future.

Neutrons are electrically neutral; they are not affected by atomic electrons or by the positive charge of the nucleus. Neutrons can pass through the atomic cloud and interact directly with the nucleus; they are highly penetrating in most materials. On the other hand, the attenuation coefficient of $\gamma$-rays for most elements decreases monotonically with energy in the range from 0.1 to 10 MeV so that $\gamma$-rays with energy $> 2$ MeV are also relatively penetrating. Thus neutron–$\gamma$ based techniques do not suffer from the limitations of penetration of X-rays and $\beta$-rays and are favored for investigating bulky materials. Sample preparation is not required. All the major elements can be assayed provided a high-resolution detector is used.

Neutron activation analysis (NAA) is an important elemental analytical technique with many applications in different fields: industry, medicine, resource exploration, forensic work, and so on.

2.1 Physical Principles

When a material is bombarded with neutrons, a neutron can be captured by a nucleus, forming a compound nucleus. The compound nucleus remains for a certain time in a highly excited state due to the addition of the binding energy of the neutron to the nucleus. It will lose this energy by the emission of one or more $\gamma$-rays (prompt $\gamma$-rays) and eventually one or more particles.
PROMPT $\gamma$-NEUTRON ACTIVATION ANALYSIS

namely one neutron (inelastic scattering), which can be accompanied by several $\gamma$-rays. After the emission of this primary radiation, the daughter nucleus can remain unstable (radioactive), decaying to the ground state by a $\beta$-decay process, followed by $\gamma$-emission (delayed $\gamma$-rays).

As shown in Figure 1, the de-excitation of the compound nucleus may take the form of a stepwise process, which can be very complex, originating a spectrum with a large number of lines (89 for Si, 449 for Cl, 113 for Ca and 187 for Fe). Most of these lines have a very small relative intensity. The large number of emitted photons is due to (1) the high binding energy of the compound nucleus and (2) the narrowing of the energy gap between levels with increasing excitation energy. Two other causes of the increase in the number of lines in a spectrum must also be taken into account: (1) every isotope has its own decay scheme and (2) the high-energy $\gamma$-photons may interact through pair production in the detector. The subsequent positron annihilation originates the emission of two 0.511 MeV $\gamma$-rays. One or both of these $\gamma$-rays may escape the detector. This means that every $\gamma$-line may be split in three lines (the full $f$, with energy $E_\gamma$; the single escape $s$, with energy $E_\gamma - 0.511$ MeV; and the double escape $d$, with energy $E_\gamma - 1.022$ MeV. The $\gamma$-ray spectrum is a signature of the sample elemental composition. The intensity of the lines is proportional to the weight content of the respective element.

Prompt $\gamma$-rays are emitted within $10^{-14}$ s of the interaction; delayed $\gamma$-rays originate in the decay of induced radioactivity. Two types of activation analysis can, then, be used: PGNAA when information is derived from prompt $\gamma$-rays and conventional instrumental neutron activation analysis (INAA) or DGNAA, where information is derived from delayed $\gamma$-rays (Figure 2). In the second case, the irradiated samples are normally removed from the irradiation position to detect the delayed $\gamma$-rays.

PGNAA is based on the analysis of a few $\gamma$-lines for each element. The selection of these lines takes into account their intensity and interference from other lines.

Two physical mechanisms predominate in PGNAA: thermal neutron capture reactions $(n, \gamma)$ and fast neutron inelastic scattering $(n,n'\gamma)$.

**Thermal neutron capture**

$$^4X(n, \gamma)^{A+1}X^* \quad ^{27}_{13}\text{Al}(n, \gamma)^{28}_{13}\text{Al}$$

$$E_\gamma = 7.724 \text{ MeV}$$

**Fast neutron inelastic scattering**

$$^4X(n, n'\gamma)^{A+1}X^*$$

Inelastic scattering \( \frac{1}{2}X(n,n')X^* \) \( ^{208}\text{Pb}(n,n')^{208}\text{Pb} \) \( E_r = 2.615\) MeV

For every nucleus there is a definite probability (cross-section) of thermal neutron capture (\( \sigma_{th} \)) and/or inelastic scattering (\( \sigma_{14\text{MeV}} \)), as shown in Table 1.

The larger the cross-section the larger the number of nuclear reactions for a given isotopic abundance in the sample and a given neutron flux and, generally, the higher the sensitivity of the method.

For a homogeneous sample the count rate, \( R_{ij} \), in \( \gamma \)-peak \( i \) from element \( j \) is given by the expression in Equation (1):

\[
R_{ij} = \frac{N_A w_j}{4 \pi M_j} \int_{E_a}^{E_v} \Phi(E_m, \tilde{r}) \sigma_j(E_m) \left( \frac{\exp(-\mu(E_i)r_d)}{r_d^2} \right) dE_m dV
\]

where \( N_A \) is the Avogadro number; \( w_j \), the weight content of element \( j \); \( M_j \), the atomic mass; \( \rho \), the bulk density \( (\rho = w_j \times \rho) \) is the mass of element \( j \); \( I_{ij} \), the number of photons pertaining to element \( j \), with energy \( E_i \), emitted per neutron captured; \( \epsilon_i \), the detector efficiency for photons of energy \( E_i \); \( \Phi(E_m, \tilde{r}) \), the energy-dependent neutron flux, at position \( \tilde{r} \); \( \sigma_j(E_m) \), the average element microscopic cross-section for the nuclear reaction that originates the \( \gamma \)-line of interest; \( r_d \), the path in the medium along the line drawn through volume element \( dV \) and the detection position; \( \mu(E_i) \), the mass attenuation coefficient; and \( S \), the detector surface.

When the energy dependence of the neutron flux inside the medium does not vary with position, the flux dependence on \( E_n \) and \( r \) can be separated. This happens, for instance, throughout the volume of a moderating material such as coal(2,3) when using \( ^{241}\text{Am-Be}, ^{252}\text{Cf} \) or 14 MeV neutron sources. Also the thermal and fast neutron fluxes can be formally separated and the neutron flux can be written as Equation (2):

\[
\Phi(E_n, \tilde{r}) = \Phi_{th}^0 \Phi_{th}(E_n) \Phi_{th}(\tilde{r}) + \Phi_{f}^0 \Phi_{f}(E_n) \Phi_{f}(\tilde{r})
\]

where \( \Phi_{th} \) and \( \Phi_{f} \) refer, respectively, to the thermal and the fast neutron fluxes. The energy dependence of the thermal component can be approximated by a Maxwell distribution and this will be indicated in the following formula by substituting \( M \) for \( \Phi_{th}(E_n) \).

Equation (1) can thus be rewritten as Equation (3):

\[
R_{ij}^C = \frac{N_A m_j}{4 \pi M_j} I_{ij} \epsilon_i \Phi_{th}^0 E_n \Phi_{M,F}(E_n) \sigma_j(E_m) dE_m
\]

\[
\times \Phi_{th}(\tilde{r}) \left( \frac{\exp(-\mu(E_i)r_d)}{r_d^2} \right) d\tilde{r}_d dV
\]

where the superscripts \( I \) and \( C \) refer to \( (n,n') \) and \( (n,\gamma) \) reactions, respectively. Equation (3) gives the count rate, \( R_{ij}^C \), arising from the fast component of the neutron flux or gives the count rate, \( R_{ij}^C \), coming from the thermal component of the neutron flux. For most elements the thermal neutron capture predominates. In fact, in most applications the information derived from the detector count rate originates in thermal neutron reactions (thermal PGNAA); in certain special cases, however, fast neutrons are used to obtain information on the sample composition (fast PGNAA). Taking into account that the Maxwellian distribution has the expression in Equation (4):

\[
\Phi_{M}(E_n) = \frac{1}{(kT)^2} E \exp\left(-\frac{E}{kT}\right)
\]

where \( k \) is the Boltzmann constant and \( T \) the neutron temperature, Equation (3) takes the form, Equation (5):

\[
R_{ij}^C = \frac{N_A m_j}{4 \pi M_j} I_{ij} \epsilon_i \Phi_{th}^0 E_n \frac{1}{(kT)^2} E_n \exp\left(-\frac{E_n}{kT}\right) \sigma_j(E_m) dE_n
\]

\[
\times \Phi_{th}(\tilde{r}) \left( \frac{\exp(-\mu(E_i)r_d)}{r_d^2} \right) d\tilde{r}_d dV
\]

\[
= \frac{N_A m_j}{4 \pi M_j} I_{ij} \epsilon_i \Phi_{th}^0 \Phi_{1}(\tilde{r}) \left( \frac{\exp(-\mu(E_i)r_d)}{r_d^2} \right) d\tilde{r}_d dV
\]

where \( \sigma_{1,0} \) is the element averaged \( 2200\) m s\(^{-1}\) neutron capture cross-section.

This equation shows that the count rate from a given line is proportional to the sample content of element \( j \). However when a perturbation of the fast neutron flux is
caused by the sample, as happens currently in applications using isotopic neutron sources and large samples, the volume integral depends on the sample bulk density and composition, particularly on the water content. Fast neutrons emitted by the neutron source are generally moderated inside the sample. An increase of the bulk density and/or of the water content (or hydrogen content), will increase the thermal neutron flux and, consequently, the reaction rate. On the other hand, increasing the bulk density will increase the attenuation of photons inside the sample. The two effects have, thus, opposite signs and can cancel each other. An optimized design of the measuring arrangement (geometry, proper choice of sample size, amount of external thermalization) can make the volume integral essentially independent of sample density and composition.

In certain cases it is important to take into account the contribution of the epithermal neutrons to the detector count rate. To this end the thermal neutron cross-section can be substituted by the quantity shown in Equation (6):

\[ g\sigma_{t,0} + I_0\frac{\Phi_{\text{epi}}}{\Phi_{\text{th}}} \]

where \( \Phi_{\text{epi}} \) is the epithermal flux, \( g \) is the Wescott constant and \( I_0 \) the resonance integral, Equation (7):

\[ I_0 = \frac{\infty}{E_{\text{th}}} \sigma(E) \frac{dE}{E} \]

### 2.2 Detectability and Sensitivity

In Equation (5) the quantity \( S_t = I_0/\lambda \) is constant for a given \( \gamma \)-ray pertaining to a given element. \( S_t \) is called sensitivity factor or index and is a useful measure of the relative sensitivity of the method for different elements under the same experimental conditions. Table 2 shows selected sensitivity factors of different elements when using gamma energies above 2.223 MeV.

Examination of the data shows that certain elements can be very easily detected by PGNAA. These include H, B, Cl, Sc, Ti, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, Cd, Dy, Au and Hg.

For thermal PGNAA to be appropriate for the detection of an element it is not sufficient that the element has a high sensitivity factor. It is important that the useful gamma lines of the element show a high spectral contrast.

</table>

* In the case of B, the sensitivity can be enhanced (approx. 73) if the 0.48 MeV \( \gamma \)-ray from the reaction \( ^{10}\text{B}(n,\alpha) \) is detected. This is usually only done when the low energy gamma background does not disturb the measurement.
i.e. a high ratio of the line intensity to that of neighboring lines pertaining to other elements.

The sensitivity factor gives qualitative information only: elements with high sensitivity factors will be more easily detected in a complex matrix. However, it is necessary to quantify the feasibility of measuring an element. Two quantities are normally considered: the absolute sensitivity (in counts s\(^{-1}\) mg\(^{-1}\)) and the DL (in µg g\(^{-1}\)).

The DL is related to the absolute sensitivity, \(S\), through Equation (8):

\[
DL = 3.29 \frac{\sqrt{R_b/t}}{S}
\]  

(8)

where \(R_b\) is the background count rate and \(t\) is the counting time.

Actual values of DL (or \(S\)) for a given arrangement and element are determined experimentally.

The two quantities, \(S\) and DL, depend on intrinsic sample characteristics related to nuclear properties of the elements (cross-section; number of \(\gamma\)-rays emitted and atomic mass; matrix interferences) and on parameters of the measuring arrangement (neutron spectrum and flux, sample dimensions, detector efficiency and resolution, background). For example, a reactor-based facility using a cold neutron source, guide tubes and a high-resolution germanium detector with Compton suppression, will normally show higher absolute sensitivity (lower DLs) than an arrangement using an isotopic neutron source for on-line measurement of large samples conveyed on a belt.

The actual DLs vary from one arrangement to another, depending on the neutron flux in the sample, the distance between sample and detector and the background due to shielding. The DL of an element can be affected by interferences from other elements present in the sample or in shielding or structural materials.

The elemental DLs for reactor-based PGNAA facilities are usually much lower than those of facilities with isotopic sources, used in on-line measurements.

As an example, Table 3 shows the DLs of the PGNAA facility installed at the Cold Neutron Research Facility of the National Institute of Standards and Technology (NIST).

#### 2.3 Prompt Versus Delayed Neutron Activation Analysis

As a laboratory analytical technique for routine sample analysis, PGNAA is generally complementary to the conventional delayed NAA systems installed at most research reactors. In contrast to DGNAA, the method is in principle applicable to all elements. As irradiation and measurement are carried out simultaneously, true multielement analysis is possible in a single measurement, at the expense of extremely complex \(\gamma\)-ray spectra.

DGNAA however is used intensively and is preferred for the determination of a large number of elements where no restrictions apply to handling and preparation of the sample. This is so because of the possibility of using higher neutron fluxes and of postirradiation counting that allow for background reduction and lower DLs.

In PGNAA arrangements installed at reactor facilities a wide variety of samples, e.g. liquids, solids, gases, museum objects, hazardous materials, can be irradiated using extracted beams that have fewer limitations on sample size and composition. In all cases neutron fluxes used in PGNAA are currently one or more orders of magnitude lower than those used in DGNAA.

The PGNAA technique is best suited for measuring elements: (1) with extremely high neutron capture cross-section; (2) elements which decay too rapidly to be measured by DGNAA; and (3) elements which produce only stable isotopes or radioactive isotopes with low gamma decay probability.

Sample preparation is not needed for PGNAA, and the results are obtained immediately. The irradiated samples may be large, which is advantageous when a representative average for nonhomogeneous material is needed. (The accuracy of the results may be affected by the presence of inhomogeneities that influence significantly the neutron flux distribution in the sample bulk and/or the position-dependent gamma attenuation.) However, large-sized samples may lead to problems due to neutron self-shielding, and specially due to neutron scattering, particularly in hydrogen.

The main advantages of the PGNAA technique are summarized in Table 4. Foremost among the advantages are nondestructiveness and the fact that nearly all elements yield a detectable signal. On the other hand, the most significant handicap is higher DLs, which restricts the number of elements that can be measured at trace concentrations and the long irradiation times often required.
Table 4 Advantages and disadvantages of PGNAA compared with DGNAA

</tbody>
</table>

While comparing different NAA techniques mention should be made of pulsed NAA, a technique that borrows some features from both PGNAA and for DGNAA. Pulsed neutron sources, e.g. neutron generators, are used so that between pulses the delayed gamma emission from the sample can be detected separately from the prompt gammas. This approach can lead to enhanced signal-to-background ratios in specific situations.

3 EQUIPMENT

3.1 General

According to the physical principle of PGNAA an operational arrangement must include a neutron source, a detection system with appropriate electronics and adequate shielding for radiological safety purposes. Generally, a dedicated computer forms the interface between the equipment and the user.

The specific objective for which the PGNAA device is designed (nature of the samples, elements to be measured, type of nuclear reactions, expected $\gamma$-ray spectrum) determines the type of source, the detector and the electronics as well as the manner in which they are assembled. An arrangement for on-line control of an industrial process in a factory or an analyzer installed at the end of a neutron guide tube have quite different designs.

3.2 Neutron Sources

The choice of the neutron source is determined not only by requirements concerning nuclear parameters such as neutron energy and flux, and half-life (when an isotopic source is considered), but also by the specific conditions regarding its utilization. Different kinds of sources are available: isotopic sources, neutron generators, nuclear reactors and spallation sources.

3.2.1 Isotopic Neutron Sources

There are two types of isotopic neutron source used in PGNAA: $(\alpha,n)$ sources and fission sources.

Sources of the first type are based in $(\alpha,n)$ reactions of isotopes that have large cross-sections for neutron production. Beryllium is an outstanding example. The sources consist of a mixture of beryllium and an $\alpha$-emitter such as polonium or americium, the whole contained in a sealed capsule:

$$^{4}_2\text{He} + ^{9}_4\text{Be} \rightarrow ^{1}_0\text{n} + ^{12}_6\text{C}$$

However, only a small number of $\alpha$-particles ($1 \times 10^4$) is effective in the production of neutrons so that the yield of the sources is relatively small. Also a background of $\gamma$-rays is present that is inconvenient for the application of the technique. Table 5 shows the main characteristics of several beryllium $(\alpha,n)$ sources.

Taking into account the neutron yield, the half-life of the $\alpha$-emitter and the $\gamma$-background, the $^{241}\text{Am}$ isotope is currently preferred. There are $^{241}\text{Am}$-Be sources commercially available up to 925 GBq.$^{(6)}$

</table>
Spontaneous fission sources can be found in the region of the transuranium elements where the α-decay instability competes with spontaneous fission. However, the half-lives of the transuranium elements are generally very short. The only nuclide with an acceptable half-life for use in applications is 252Cf ($T_{1/2} = 2.645$ y). This nuclide decays by α emission in 97% of the cases and by spontaneous fission in the remaining 3%. The average number of neutrons emitted per fission is 3.76. A source containing $3 \times 10^{10}$ Bq of 252Cf has a neutron yield of $4.3 \times 10^9$ ns$^{-1}$, which is three orders of magnitude higher than that of the more interesting (α,n) sources. The γ-dose at 1 m from a source emitting $10^6$ ns$^{-1}$ is 0.0007 mGy h$^{-1}$ (a factor of 10 smaller than for a 241Am-Be source). The average neutron energy of a 252Cf source is 2.3 MeV.

In Figure 3 neutron spectra and γ-spectra for Cf and Am-Be sources are plotted for comparison. The high specific activity of the Cf source is an advantage over the (α,n) sources. Other advantages are small size and low heat and gas generation, which decreases the risk of source damage for long-term operation. These radioisotope sources are used in PGNAA devices designed for field work.

3.2.2 Neutron Generators
Sealed tube neutron generators$^{(9,10)}$ are based on the following reactions:

\[ _1^2\text{H} + _1^2\text{H} \rightarrow _2^4\text{He}(3.6\,\text{MeV}) + _1^1\text{n}(14.1\,\text{MeV}) \]
\[ _1^2\text{H} + _1^3\text{T} \rightarrow _2^3\text{He}(0.8\,\text{MeV}) + _1^1\text{n}(2.45\,\text{MeV}) \]

In generators emitting 14.1-MeV neutrons, a deuterium ion beam (or a mixture of deuterium and tritium ions) is accelerated up to between 70 and 300 kV and made to impinge on a tritiated target (or a deuterated and tritiated target). In the latter case 2.45-MeV neutrons are also produced. However, the emission of 14.1-MeV neutrons dominates. It is possible to obtain an emission rate of $10^{11}$ ns$^{-1}$.

Tubes emitting 2.45-MeV neutrons are based on deuterium–deuterium reactions, i.e. a beam of deuterium ions is accelerated up to a few hundred kilovolts and impinges on a deuteron target. Neutron emission of such tubes may reach $10^{10}$ ns$^{-1}$.

A great advantage of neutron generator tubes is the possibility of on/off switching, i.e. the production of neutrons is stopped whenever required. Another interesting characteristic is the possibility of pulsing the neutron beam.

The lifetime of a sealed tube is limited by target heating and target sputtering from ion beam impurities.

A new neutron generator source has been presented: the inertial electrostatic confinement (IEC) device. The IEC device is a neutron source where deuteron ions are accelerated producing fusion reactions as they react with a deuterium plasma target. Commercially available units deliver $10^7$ of 2.45-MeV n s$^{-1}$ during steady-state operation. The neutron emission is isotropic. It is a practical low-to-medium-yield source for laboratory and industrial applications.$^{(11)}$

3.2.3 Nuclear Reactors
Nuclear reactors are still the most important neutron sources. The thermal neutron flux of a reactor source
is of the order of $10^{13}$ n cm$^{-2}$ s$^{-1}$ up to $10^{15}$ n cm$^{-2}$ s$^{-1}$. The neutron energy spectrum can be divided into three components: fast, epithermal and thermal. Their relative importance is dependent on the reactor structure. Usually, the thermal neutrons constitute the most intense fraction. Thermal neutrons are in thermal equilibrium with the atoms of the reactor moderator; their most probable energy equals $kT$ (where $k$ is Boltzmann’s constant and $T$ is the neutron temperature). At room temperature the most probable energy is 0.025 eV. Epithermal neutrons have energies from $5kT$ to 0.8 MeV. Fast neutrons have energies $>0.8$ MeV.

PGNAA facilities are usually installed at the extraction end of a neutron beam tube (sometimes using a neutron guide). The performance can be enhanced by using subthermal or “cold” neutrons. These neutrons have energies lower than 10 meV. Cold neutrons are extracted from a cooled moderator placed in the neighborhood of the reactor core. The moderator may be liquid hydrogen or deuterium at about 30 K. Occasionally, liquid methane is also used at temperatures of about 100 K. The cold neutron absorption cross-section for most elements is about two to three times greater than that for thermal neutrons ($1/\nu$ behavior).

Owing to their long wavelength, about 0.3 nm, cold neutrons can be bent out of the flight path followed by higher energy radiations by using curved neutron guides. As a consequence, such cold neutron beams display a much lower $\gamma$ and fast neutron background. Figure 4 shows the Cold Neutron Research Facility at NIST.

### 3.2.4 Neutron Spallation Sources

The operation of a neutron spallation source is, in principle, similar to that of an X-ray tube. Protons are accelerated to a high energy, in the range of hundreds of megaelectronvolts (typically 800 MeV up to 1 GeV) and directed on to a heavy metal target, such as uranium, tungsten, lead or a liquid metal (mercury). The result is excitation of the target nuclei. Their de-excitation is accomplished by the emission of several neutrons per incident proton (the number shows an energy dependence and may reach 30). Most of the neutrons produced have energies similar to those of a fission spectrum.

Neutron spallation sources can be continuous or pulsed. A typical value of the neutron flux from a continuous spallation source is $10^{13} - 10^{14}$ n cm$^{-2}$ s$^{-1}$.

Figure 5 shows the Paul Scherrer Institute spallation neutron source SINQ.

### 3.3 Shielding

The shielding of a PGNAA facility must be designed according to the neutron source used. Shielding problems for on-line systems are completely different from those of an analyzer installed at the end of a neutron guide tube in a reactor hall. The shielding has two major functions: reducing the detector background so as to enhance the signal to background ratio and guaranteeing radiological safety.

Radiation coming directly from the neutron source as well as that originating in interactions within the sample and components of the system (structure, shielding) can be classified in four groups: (1) fast and epithermal neutrons, (2) thermal and cold neutrons, (3) primary $\gamma$-radiation and (4) secondary $\gamma$-radiation.

#### 3.3.1 Fast and Epithermal Neutrons

The absorption cross-section of fast and epithermal neutrons is small for all materials. For this reason, it is necessary to slow down the neutrons before capture. The most effective shield for these neutrons is a mixture of a hydrogenous material and a thermal neutron absorber.

#### 3.3.2 Thermal and Cold Neutrons

A few elements, such as boron, lithium, cadmium and gadolinium, have a high cross-section for thermal and cold neutrons. Compounds of these elements can be used to obtain an effective shielding against these neutrons.

Neutron absorption in boron and cadmium is followed by the emission of $\gamma$-rays. This emission must be taken into account in the design of the shielding of the facility.

#### 3.3.3 Primary $\gamma$-rays

Primary $\gamma$-rays are emitted directly by the neutron source. The problem is particularly acute in on-line analyzers using isotopic neutron sources. The source is generally surrounded by a layer of a strong $\gamma$-ray absorber such as lead or bismuth.

#### 3.3.4 Secondary $\gamma$-rays

Secondary $\gamma$-rays originate in $(n,\gamma)$ or $(n,n\gamma)$ reactions that take place within the sample or in shielding and structural materials. Only $\gamma$-rays from the sample directed towards the detector are wanted for the analysis. Adequate shielding must be provided to absorb all other $\gamma$-rays.

#### 3.3.5 Composite Shielding

A good shielding material for neutrons is a mixture of a hydrogenous material and a good thermal neutron
Figure 4 Experimental facilities around the NIST Reactor. A PGNA facility is represented. (Reproduced from Paul et al. with permission.)
absorber. Polyethylene with addition of boron or lithium has proven to make a good shielding because of the physical and chemical properties of the composite: high density of hydrogen atoms, chemical inertness and ease of machining. Lithium–polyethylene materials are very useful as detector shielding because lithium generates no capture γ-rays. Other hydrogenous materials, such as water or paraffin, are not advisable for industrial applications because of fire hazards and the possibility of leakage that can jeopardize safety.

A combination of lead and boron–polyethylene makes a material with good shielding properties for mixed neutron–γ fields.

3.4 Detectors

The criteria for the choice of a γ-ray detector must take into consideration efficiency, resolution, sensitivity to neutron damage and maintenance.

Essentially two types of detector are used in PGNAA. Scintillation detectors based on a thallium-doped sodium iodide detector, (NaI(Tl)), or a bismuth germanate detector (Bi$_4$Ge$_3$O$_{12}$), (BGO), and solid-state germanium detectors, normally the n-type hyper-pure germanium detector (HPGe). Resolution, efficiency and maintenance care are different for the two detector types.

The HPGe detector shows the best resolution, approximately 0.1% fwhm (full width at half-maximum). The NaI(Tl) scintillator has a resolution of about 5% at 2 MeV, or 3% at 10 MeV; the BGO scintillator has the poorest resolution, about a factor of two lower than that of NaI(Tl). The resolution of the HPGe detector enables the separation of closely spaced γ-lines in complex spectra.

Regarding efficiency, HPGe detector units currently used normally have lower efficiencies than BGO and NaI(Tl) detector units. However, HPGe detectors can have relative efficiencies (compared to a standard NaI(Tl) detector) of the order of 1, if a large enough germanium crystal is used, with the corresponding high cost. The HPGe detector is the most sensitive to neutron interactions within the crystal that promote the formation of traps causing resolution degradation. Owing to the mechanism of transport of charged particles inside the crystal, the n-type detector is less sensitive to neutron damage than the p-type.

Finally, HPGe detectors must be operated at low temperature (100 K) requiring expensive maintenance services. This is a drawback for on-line applications in industry.

Frequently an association of different detectors is used to optimize the arrangement (HPGe/NaI(Tl) or HPGe/BGO).

Detectors used for on-line industrial PGNAA are in general scintillation detectors. Reactor-based analyzers predominantly use HPGe detectors.

3.5 Signal Processing and Data Handling

The main objectives of signal processing and data handling at a PGNAA facility are to maximize the pulse throughput rates and minimize the γ-ray background without detriment to the energy resolution.

The characteristics of the signal processing system must be adapted to the type of detector and to the expected γ-ray count rates. Signal processing and data handling are carried out by a γ-spectroscopy unit.

The basic components of the γ-spectroscopy unit are the preamplifier, amplifier, analog to digital converter (ADC) and multichannel analyzer (MCA).

The function of a preamplifier is to extract the signal from the detector without significantly degrading...
the intrinsic signal-to-noise ratio. The preamplifier is located as close as possible to the detector to minimize noise.

A germanium detector represents an extremely high capacitive impedance source (10 GΩ, 10–50 pF), generating a small charge \((Q = 2.7 \times 10^{-13} \text{ C})\) in the detection of a 5-MeV particle. The small output signal requires that the preamplifier does not add appreciable noise.

The absorption of a γ-ray by the detector produces a current pulse at the preamplifier input. The preamplifiers are typically of charge sensitive configuration and are coupled to the detector through the gate of a field effect transistor (FET). Two types of these preamplifiers can be used with Ge detectors: one employs the dynamic charge restoration method (resistor capacitor feedback) and the other the pulsed charge restoration method (pulsed optical or transistor reset) to discharge the integrator.

In many high count rate and high-resolution applications the transistor reset preamplifiers (TRP) offer the best performance.

Nowadays advanced hybrid-electronics manufacturing capability allows the incorporation of the detector element, preamplifier and high-voltage filter into a compact streamlined system.

Where the resolution is not a vital system parameter it is not necessary to use Ge detectors. In their place scintillation detectors can be used. A scintillation detector coupled to a photomultiplier tube generates moderately large signals at the output thus relaxing restrictions on the noise contribution from the preamplifier. They can be also associated with charge sensitive preamplifiers.

A main amplifier with sufficient linearity and large enough bandwidth extracts the energy information from the preamplifier output and converts it to a shape that can be easily analyzed by an ADC. The first stage of the amplifier (differentiator) reduces the decay time and blocks the low frequency or direct current components in the input signal. The following stage (integrator) recovers the energy information from the signal. This yields Gaussian-shaped pulses. The amplitude of each pulse is directly proportional to the energy of the γ-radiation.

To process an incoming pulse completely the amplifier must be adjusted for a time constant (TC) about 10 times the input pulse rise time. A shorter TC stops the processing before it has reached its maximum amplitude, which means loss of resolution in the data. But a longer TC means longer amplifier processing time, which reduces the throughput capabilities of the amplifier: if a new pulse reaches the amplifier before processing the previous one, a pile-up occurs and the piled up pulses are invalid events. Although there are ways to prevent the processing of these pulses, the net effect is decreased system output.

As a shorter shaping TC minimizes pile-up, a TC of 2 μs is recommended for good resolution with Ge detectors. Its maximum throughput capability is just under 20 kcps (kilocounts per second), which is achieved at an input count rate of about 50 kcps. If the input rate exceeds that value, throughput actually decreases owing to pulse pile-up.

For high count rates the use of a gated integrator (GI) will allow a gain of the order of 10 kcps in throughput.

In order to ensure that the piled-up events are not processed by the ADC, additional circuits must usually be considered. These circuits are called pile-up rejector/live time corrector circuit (PUR/LTC). When a new pulse arrives before the previous one is processed, the new pulse is rejected.

The ADC unit converts the amplitude of each event into a digital value to be processed by the MCA or computer. Two types of ADC are available: the Wilkinson ADC and the fixed conversion time (FCT) ADC. The FCT ADCs can offer conversion times significantly shorter than those from the Wilkinson type at least for higher energy events. The choice depends on the specific application taking into account channel resolution and signal amplitude.

The MCA or a personal computer-based MCA acquisition board collects and stores the data, provides its visualization on a monitor, performs mathematical operations to generate the final results and transfers the raw and/or the treated data to an external storage device.

Current cheap memory circuitry provides adequate numbers of data channels and counting capacities as well as short enough data storage times (no more than a couple of microseconds) to deal with the highest count rates encountered in practice.

Hanna et al.\(^{(30)}\) and Wormald\(^{(31)}\) proposed the use of compound detectors for Compton suppression and pair spectrometry. The use of coincidence/anticoincidence techniques with compound detectors can provide simpler spectra by selecting only the useful events. Pair production and Compton scattering are the most important interactions for high-energy γ-rays. If the interaction occurs within the sensitive volume of the detector and the resulting secondary γ-rays escape the detector, a smaller amplitude pulse is recorded.

Schematically, pair spectrometers use three detectors: a central one in which the primary radiation is detected by pair production, and two others for detecting the 0.511-MeV annihilation photons. An event is recorded by using coincidence techniques if a photon of \(E_\gamma - 1.022\text{ MeV}\) is registered in the central detector and, simultaneously, two 0.511 MeV photons are detected in the others. This method improves the high-energy tail of the spectrum. Wormald proposed a close packing array of cylinders or
hexagonal prisms to form a large collecting area adapted to the shape of the sample.

The Compton suppression spectrometer uses anticoincidence techniques to eliminate events resulting from Compton scattering: only signals which do not have a coincidence signal in another detector are recorded. This technique greatly simplifies the low-energy part of the spectra. A γ-ray spectrometer operating simultaneously in Compton suppression and pair production modes acquires information in three modes: single mode, Compton suppression mode and pair mode. Analysis of the complex γ-ray spectrum can be performed by comparing the three spectra. The spectrometer performance is enhanced.

A wide variety of application programs is available for data handling of the spectra (nuclide identification, background and interference corrections, peak intensity and percent weight content calculation).

4 INSTRUMENT DESIGN AND CALIBRATION

The gauge response of a PGNAA analyzer is determined in a complex manner by the system parameters – geometry, source activity and neutron energy spectrum, and detector efficiency – and by certain properties of the analyzed sample such as bulk density and water content. It follows that the count rate caused by a given γ-ray line is a nonlinear function of the concentration of the element to be measured.

The density and the dimensions of the sample have a direct effect on reaction rates in the sample volume and on the attenuation of γ-rays and thus on the γ-count rate at the detector. For a fixed geometry and composition of the sample the thermal neutron flux depends on the bulk density. When the density increases, the thermal neutron distribution is “compressed” spatially with a higher maximum shifted towards the region of the sample adjacent to the neutron source. On the other hand, the relevant γ-rays on average travel a longer way to the detector inside the sample and are subject to a stronger attenuation. These two effects act in opposite directions upon the γ-count rate and can cancel each other for particular geometries.

Furthermore, the hydrogen content of the sample may also have a significant effect on the neutron flux distribution.

In principle, the composition of an unknown sample can be derived by solving Equations (3) or (5). In this direct or absolute method the concentration of each element is calculated using fundamental parameters, such as cross-sections, number of photons emitted by the element per neutron captured, detector efficiency, γ-ray attenuation coefficients in the sample and solid angle viewed by the detector. However, this method is only applicable in a small number of cases owing to uncertainties in the available microscopic nuclear parameters, the unavailability of others and the influence of composition, density and sample volume on the count rate from a given γ-ray line. In activation analysis of large samples a number of correction factors must be applied (neutron absorption and moderation, γ-ray attenuation within the sample and detector efficiencies).

The simplest case is that of thin samples irradiated in a thermal or cold neutron beam. Neutron scattering and γ-absorption in the sample are, then, negligible thus reducing the influence of sample composition and homogeneity on the count rate.

The problem becomes more complicated for on-line gauges using isotopic neutron sources and large samples. Generally, there is neutron thermalization inside the sample so that the thermal neutron flux distribution is dependent on the sample composition, particularly on hydrogen content (moisture) and bulk density.

There are, in principle, several methods for calibrating a PGNAA gauge.

4.1 Experimental Calibration

Experimental calibration establishes the correlation between the γ-ray peak areas and the known chemical composition, density and water content of the samples. The experimental determination of the calibration curves demands long laboratory work, using a large number of standards with well-known compositions, matrix and geometry that closely match those of the sample.

The variation in a given parameter can affect the γ-count rate due to a given element, although the concentration of the element remains unchanged. It is a very time-consuming approach, because new standards must be prepared for each sample type.

4.2 k₀ Method

The k₀ method is used extensively in delayed NAA. The k₀-factor is the ratio of the absolute sensitivity divided by the detection efficiency of the γ-rays of the element to be measured compared with that of a comparator element, s, Equation (9):

\[ k_0 = \frac{R_j / m_j \varphi_j}{R_s / m_s \varphi_s} = \frac{\theta_j I_j \sigma_j / M_j}{\theta_s I_s \sigma_s / M_s} \]

where \( \theta \) is the isotopic abundance of the nuclide.

In the absence of significant γ-ray self-absorption and for elements with neutron cross-section varying as \( 1/\nu \),
the $k_0$-factor is independent of neutron energy, sample matrix and geometry.

Measurement of $k_0$-factors allows in principle accurate determinations of relative concentrations of every element contained in the sample without the use of the comparator. In effect, the relative concentration of element $j$ to element $i$ in the sample is given by the formula, Equation (10):

$$
\rho_{j,i} = \frac{m_j}{m_i} = \frac{R_{j,i}}{R_{i,i}e_{j,j}}
$$

When the concentration of one of the elements is known, the absolute concentration of any other element can be assessed. Otherwise it is necessary to measure only the sample and a single standard of the comparator. In effect, the relative concentration of element contained in the sample without the use of the comparator element to determine absolute concentrations.

There are some problems that can affect the accuracy of the $k_0$ measurements. Among them are deviations from the $1/v$ behavior of the neutron cross-sections, gamma attenuation in thick samples or with large concentrations of high-Z elements and heterogeneities in the sample.

The $k_0$ method has been applied by several authors to PGNAA measurements.\(^{36–39}\)

### 4.3 Monte Carlo Library Least Squares Technique

Gardner et al. have developed the Monte Carlo library least squares method (MCLLS) for PGNAA.\(^{40–42}\)

According to this model the PGNAA gauge is a "black box". The gauge response, $R$, is represented by the function, Equation (11):

$$
R = f(x, u, v, w, \ldots)
$$

where $x$ is the parameter to be measured and $u, v$ and $w$ represent variables that characterize the measurement interferences. Then, Equation (12):

$$
x = F(R, u, v, w, \ldots)
$$

In the linear least squares (LLS) model the spectrum of the sample is a linear combination of individual components. The content of each channel can be expressed as, Equation (13):

$$
b_i = \sum_{j=1}^{m} x_j a_{ij} + E_i \quad i = 1, n
$$

where $b_i$ is the unknown sample spectrum or counting rate in channel $i$ of the sample; $x_j$ is the amount of component $j$ in the sample; $a_{ij}$ are the library spectra or counting rate per unit amount of component $j$ in channel $i$; and $E_i$ is the random error in channel $i$ due to statistical counting rate fluctuations.

If the system is linear, i.e. if the gauge response to an individual component does not depend on other parameters, the concentration, $x_j$, can be obtained by minimizing the reduced chi-square with respect to each amount.

However, as the PGNAA analyzers are usually non-linear, the MCLLS approach has been developed. This is an iterative method that requires that a very accurate Monte Carlo code enables the calculation of the spectra of a sample given its composition, density and geometry. To this end the entire arrangement and the sample are simulated.

Simulations are performed in order to generate the elemental library spectra of all elements present in the sample. The model consists of the following steps:

1. The Monte Carlo code generates the pulse height spectrum of a sample whose composition and density are similar to that of the unknown sample.
2. The prompt $\gamma$-ray spectrum for each element is recorded separately to serve as a library spectrum.
3. The linear library least squares analysis is then performed using the spectra of the unknown sample and the calculated library spectra. The elemental composition obtained is compared with the initially assumed values.
4. If the calculated elemental composition of the unknown sample is close enough to the values assumed for the Monte Carlo simulation, these are taken as the final measured values. If not, the LLS values are taken for the next iteration and steps 1 through 3 are repeated until the linearity assumption is valid.

### 4.4 Monte Carlo Simulation of Calibration Curves

Another method relies on the Monte Carlo simulation of the measuring arrangement with samples having different compositions, densities, water contents and thicknesses, in order to establish the correlation between the count rate for unit concentration of an arbitrary element and the sample parameters.\(^{43}\) A comparison is then carried out between the simulated calibration curves and the experimental results obtained with a few standards. A regression analysis is carried out to adjust the simulated calibration curves to the experimental points. Although Monte Carlo simulation studies do not entirely suppress the need to carry out experimental calibration work, they considerably reduce the number of calibration standards required. This method has been used by
Oliveira et al.\textsuperscript{(44,45)} using the MCNP (Monte Carlo N-particle) code\textsuperscript{(46)} for PGNAA analysis of coals and cement raw materials.

### 4.5 Design Optimization

The crucial part of the design of a PGNAA system is that of ensuring a well-defined correspondence between the output of the system and the elemental composition of the sample. Design optimization is particularly important in the case of equipment for field use with isotopic neutron sources. With fast neutron sources, the thermal flux within the sample volume strongly depends on the moderating properties of the sample, which in turn depend on its density and the number of hydrogen atoms per unit volume, i.e., the water content. On the other hand, the average path length to the detector of γ-rays generated in the sample strongly depends on the sample dimensions. Thus, the γ-ray count rate at the detector depends on the sample bulk density and dimensions and on the spatial distribution of the thermal flux.

The purpose of design optimization is to reduce the complexity of the functional dependence of the system response relative to the chosen calibration parameters. This can be achieved in a certain range of sample parameters by acting on the sample geometry, namely the sample thickness, and on the effective neutron source spectrum modified by the introduction of a moderating material around the source or between source and detector, which will substantially influence the thermal neutron flux and its spatial distribution inside the sample.

Monte Carlo simulation is a useful method for speeding up design work and system optimization. The influence of the different parameters on the specific count rate from an element can be established by means of the simulation. Optimum design parameters mean that the gauge response is less sensitive to measurement interferences, such as the ones referred to above (fluctuations of density and water content). To reach this objective, the variance of the measured variables must be minimized with respect to both the gauge response variance and the variances of each measurement interference (see Equation 12).

### 5 APPLICATIONS OF THE METHOD

#### 5.1 Introduction

PGNAA is a powerful analytical technique that can provide accurate information about the elemental composition of materials in a broad range of cases: raw materials, mineral exploration, contaminants, detection of forbidden products, such as drugs and explosives, inspection of containers (detection of plutonium) and applications in health care. In the following sections the main fields of application of the method are briefly reviewed.

#### 5.2 Borehole Logging

Since the early 1980s, the most interesting advances in nuclear logging techniques concerned the development of spectroscopy techniques, especially for the analysis of γ-ray spectra.\textsuperscript{(47)}

Measurements of the energy spectrum of γ-rays were first applied to the detection of natural radioactivity from potassium and of unstable isotopes of the thorium and uranium decay series. Later on, neutron sources coupled to energy-sensitive detectors were used to observe γ-rays from neutron-induced reactions.

Nowadays, spectroscopy of γ-rays from thermal neutron capture and the inelastic scattering of fast neutrons is commonly used in the study of wellbore geophysics. In this type of well logging, a gauge consisting of a neutron generator or a radioisotopic fast neutron source, and γ-ray detectors is introduced through the formations in boreholes. There are applications for exploration and exploitation of mineral resources (oil, gas and coal) as well as for the study of geochemical processes.

The main interest of the oil and gas industry in this technique derives from its ability to locate porous zones that may contain hydrocarbons and are free of clay minerals whose presence would inhibit fluid flow. At the same time it must be ensured that oil and gas production do not contaminate potable water supplies. The coal industry is interested in in situ control of coal quality.

The set of detectable elements provides valuable information on the nature of rock matrix or geological formation. Previously, this information could only be obtained through discrete core analyses.

However, the proper determination of elemental concentrations requires reliable information on geophysical parameters as well as specific spectrometric information related to the individual elements. Several approaches have been developed.\textsuperscript{(48–50)}

Elemental concentrations obtained from logging measurements have been routinely used to provide sedimentary mineralogy, cation-exchange capacity, permeability and other rock and fluid properties. A comparison between mineralogy derived from logging measurements and that derived from laboratory analyses of core samples is shown in Figure 6.

Information from borehole logging during coal exploration can give an early indication of coal quality by allowing the direct determination of the concentration of sensitive elements and the derivation of important
economic parameters such as ash content and calorific value.

5.3 Industrial On-line Applications

On-line industrial applications of PGNAA are particularly important in the quality control of coal and in the fabrication of cement. Equipment for bulk analysis of coal and cement is presently commercially available. Other on-line applications in raw material control have been implemented, e.g. the determination of Al in bauxite ores\(^{(31)}\) or conveyor belt sorting of aluminum alloys in scrap.\(^{(52)}\)

The PGNAA technique surpasses the X-ray fluorescence (XRF) technique owing to the higher penetrating power of the neutron–gamma radiation, which as a consequence has the potential to analyze the whole bulk of the material stream. In these applications radioisotopic sources (generally \(^{252}\)Cf) or neutron generators are used.

The raw material can flow through a vertical chute where the analysis process occurs; generally the chute is lined with an extremely low-friction material to ensure plug free operation. Alternatively, the raw material can be conveyed on a belt. In this case physical integration of the equipment in a previously existing process line is simpler and less costly. Problems related to “dead zones” which always appear in the vertical chute are also avoided in this configuration.

The use of coal as an energy source has severe environmental consequences (ash and SO\(_2\) emissions). Good quality control in all phases of the coal fuel cycle will limit the adverse effects. PGNAA can be used in all phases of the coal cycle: mining, coal preparation and power station operation, for the determination of ash, moisture content and specific energy. Among the major coal elements, hydrogen and iron give the best response; sulfur and many of the ash elements (Si, Al, Ti, Ca, Mg, Na, K) are also satisfactorily detected. Carbon responds poorly; however, as its concentration is high it can be detected. Oxygen can hardly be detected in the \(\gamma\)-spectrum due to the element’s very small thermal neutron capture cross-section. However, oxygen and carbon can be easily detected using \((n,n'\gamma)\) reactions, whose threshold energies are, respectively, 6.13 MeV and 4.44 MeV. This implies the use of a 14-MeV neutron generator or of \(^{241}\)Am-Be as the neutron source.\(^{(53)}\)

Figure 7 shows an experimental prompt $\gamma$-ray spectrum of a coal.

The cement industry is fundamentally interested in the measurement of silicon, aluminum, iron and calcium oxides. All the elements involved (except oxygen) can be determined by PGNAA.\(^{54}\)

The most common application in the fabrication of cement is raw mix proportioning, with the analyzer positioned just ahead of the raw mill. Real-time results can be used to make frequent adjustments of the component feeders to keep the raw mix close to reference composition; another application is the analysis of raw material as it enters the preblending pile. As an alternative to mechanical samplers, analyzers can reduce maintenance and labor costs. A third application is the sorting of raw material coming from the quarry. When synchronized with a downstream diverter, the analyzer can be used to sort one-minute increments of material into save or reject piles.

5.4 Medical In Vivo Applications

In vivo neutron activation analysis (IVNAA) is a unique direct in vivo method for the multielemental analysis of the living human body. Various other radiation-based techniques (radiography, isotopic imaging, radiotracer dilution) reflect only relative changes in tissue density or volume. Table 6 shows the elements measured by activation analysis.\(^{55}\)

The prompt $\gamma$-variety of IVNAA can provide data on the total or partial body content of the following elements: oxygen, carbon, hydrogen, nitrogen, calcium, sodium, chlorine, silicon, iron, cadmium and mercury.

Although PGNAA instruments were initially developed in nuclear research laboratories, methodologies have advanced to a stage where facilities were designed and built exclusively for clinical application in hospitals and health centres.

The choice of the neutron source is based on elements to be measured, the required degree of uniformity of the activation, the acceptable level of accuracy and the admissible radiation dose. Cf and Pu-Be are the most used sources; some facilities are equipped with neutron generators or cyclotrons. Large NaI(Tl) scintillators are generally used as detectors, although in certain facilities germanium or BGO detectors are preferred.

Considerable effort has been expended in reducing the absorbed dose without decreasing the precision of results. The substitution of Pu-Be sources by Cf contributes to this end. The range of exposure doses in existing facilities depends in part on the element to
The initial application that has influenced the subsequent development of IVNAA is the determination of total body calcium content in patients suffering from various metabolic diseases. Since calcium is predominantly located in the skeleton, a measure of this element would provide a direct examination of the total skeletal mass. Clinical research studies have investigated a number of metabolic disorders in which there is a primary or secondary alteration of mineral metabolism: osteoporosis, osteomalacia, renal osteodystrophy, Paget’s disease, Cushing’s syndrome, acromegaly, thyroid and parathyroid disorders, myotonic dystrophy, thalassemia and alcoholic cirrhosis.

The body nitrogen measurement provides a direct determination of body protein, which is the essential component of the body’s lean tissue mass. Changes in protein mass can reflect changes in nutritional status. Hence clinical studies involving nitrogen measurements in patients with progressive diseases may be important in the following cases: postoperative surgery, protein malnutrition, cancer renal failure, cardiovascular disease, total parental nutrition, obesity and growth deficiencies.

Body carbon measurements can provide an index of the body fat.

Cadmium measurements have been carried out in industrial workers. Kidney concentrates cadmium and has been identified as the initial target organ in toxicological studies. The association between cadmium burdens and various diseases related to kidney malfunctions have also

been investigated. Several studies involving nondialed patients in renal failure have shown that cadmium was a cofactor in the cause of the renal disease.

5.5 Determination of Environmental Contaminants

Elemental analysis of toxic elements in contaminated materials is essential for solving environmental problems. PGNAA can also be applied to this purpose in the determination of major and minor elemental components and even of trace elements.

Dulloo et al.\(^\text{57}\) used a 14-MeV pulsed generator for the nondestructive assay of mercury, cadmium and lead. The DLs for a 600 s run are 15 ppm, 170 ppm and 8600 ppm for Cd, Hg and Pb respectively.

Yonezawa et al.\(^\text{23}\) carried out multielement analysis of environmental samples by PGNAA with cold and thermal neutrons in a reactor facility. Cd was detected in mussels, river sediments, pond sediments, vehicle exhaust particulates and unpolished rice flour; Hg was detected in human hair.

Hiep and Tan\(^\text{22}\) used the technique for analyzing the concentration of Al, Fe, Ti, Si, Ca and K in airborne dust samples.

5.6 Explosives and Drugs Detection Systems

Considerable progress has been made in research and development of nuclear-based techniques for the detection of explosives and drugs. The technique must be noninvasive, sensitive to the smallest effective amounts of explosives and drugs and give rise to a minimum of false alarms. An effective contraband inspection system must be capable of determining the relevant chemical elements and their spatial distribution in the inspected object.\(^\text{58}\)

Chemical explosives have high nitrogen and oxygen contents. Pure narcotics are characterized by high content of H and C, moderate content of O and small content of N. However, narcotics hydrochlorides also contain small amounts of Cl. While high nitrogen density is a good indicator of explosives, the detection of a low oxygen to carbon ratio combined with the presence of N and Cl is a strong indication of the presence of drugs.

The PGNAA technique enables the three-dimensional mapping of explosives and narcotics in luggage. This is accomplished by irradiating parts of the interrogated object with short pulses of fast monoenergetic neutrons (Figure 9). The three-dimensional distribution can be obtained by scanning the sample.\(^\text{59}\)

5.7 Other Applications

Many other applications have been carried out in different fields using PGNAA.

Anderson et al.\(^\text{60}\) described the determination of H, B, Cl, K, Na, S, Ca and Cd in foods using a thermal neutron beam. The advantage of this type of analysis lies in its sensitivity to elements of nutritional or toxicological interest while no sample preparation is needed, thus eliminating the risk of volatilization losses.

Kuno et al.\(^\text{61}\) applied PGNAA to the determination of the concentration of B, H, S and Si in on-shore sediments in order to investigate the distribution and migration of chemical elements. The measurements were complemented by DGNAA results.

Caffrey et al.\(^\text{62}\) applied a portable PGNAA device with an isotopic source to the identification of the contents of munitions, chemical storage containers, chemical warfare materials in stockpiles, etc.

Prettyman et al.\(^\text{63}\) investigated the use of the technique as a diagnostic tool related to matrix characterization for nondestructive assay and plutonium surveillance. The technique can help to confirm item descriptions (for example, plutonium chloride versus plutonium oxide).

Spyrou et al.\(^\text{64}\) proposed a method to determine the concentration of a large number of elements by measuring the prompt or delayed γ-rays and applying the principles of reconstructive tomography to obtain the spatial distribution of elemental concentration in a selected plane or slice through the sample. This method has been employed in the examination of radioactive waste as well as in elemental analysis of biomedical and bioenvironmental samples.

The contents of major and some trace elements in large archaeological materials have been determined by Sueki et al.\(^\text{24}\)
6 PRESENT TRENDS OF DEVELOPMENT

According to Gardner\(^{(52)}\) “PGNAA is a rapidly emerging important new technology and measurement approach”. However, further development of its applications in different branches of human activity require improvements in neutron sources, signal processing and data handling as well as in nuclear data.

The introduction of a new point source generator based on the IEC principle may have a promising future in on-line field applications of PGNAA. Apart from sharing the on-off switching capability with conventional neutron generator devices, it offers longer life and lower costs.

Industrial on-line process control requires short response times. For a PGNAA analyzer this means, normally, high count rates. High-rate data acquisition systems must be improved.

Enhancement of signal to background noise ratio leads to lower statistical uncertainty of the results thus contributing to reducing response times. This objective can be achieved by proper system design optimization. Monte Carlo methods can play an important role in this respect.

More accurate measurements and thus better data regarding microscopic nuclear parameters, such as cross-sections, number of photons emitted per neutron captured by the relevant isotope and \(\gamma\)-ray attenuation coefficients in different materials are important for simulation studies carried out with a view to optimizing design and calibration of PGNAA analyzers.

Although certain physical constraints (neutron flux perturbations and \(\gamma\)-ray attenuation) are difficult to overcome, the development and application of the \(k_0\) method to large samples would be welcome.

The MCLLS technique, which has been applied to coal, cement raw materials, oil well logging, vitrified nuclear waste and conveyor belt sorting of aluminum alloys in scrap, can also be successfully applied to other fields.

The nuclear imaging technique using a pulsed fast neutron analyzer for the detection of explosives concealed in airline luggage has potential application in the future to a variety of other situations.

ACKNOWLEDGMENTS

The authors wish to thank our colleagues Carlos Cruz for helpful discussions concerning signal processing and data handling, António Falcão for his contribution in graphics design of Figures 1 and 2 and Teresa Pires for her improvements in graphics in Figures 3, 6, 7, 8 and 9.

Radiochemical neutron activation analysis (RNAA) is a method for trace-element determination based on the measurement of an indicator radionuclide, chemically separated from a neutron-activated sample. Unlike instrumental neutron activation analysis (INAA) the RNAA is therefore not a nondestructive method, and at the same time the amount of work put into the analysis of each sample makes RNAA much more expensive than INAA. This is the cost that has to be paid for determining selected elements at much lower concentrations and superior accuracy, while maintaining matrix independence and most of the other excellent characteristics of INAA. One of these characteristics is the small self-shielding during irradiation with neutrons, which opens the possibility of analyzing also large samples without any pretreatment.

Particularly for the lowest levels of trace elements RNAA provides several important advantages over alternative analytical methods:

a) the absence of a reagent blank, and
b) the corresponding insensitivity to contamination after activation
c) the controlled addition of carrier to avoid losses by adsorption etc., and
d) the corresponding possibility of determining chemical yield or recovery.

When carefully and thoughtfully carried out, RNAA qualifies as a so-called definitive method, one of the reasons being its direct traceability to a comparator of the pure element to be determined.

1 INTRODUCTION

The use of neutrons for analytical purposes goes back to the classical paper by Hevesy and Levi, who discovered in 1936 in Copenhagen that activation of a sample of presumably pure Y₂O₃ by means of a Ra–Be neutron source gave rise to a radionuclide that could only be attributed to Dy; by comparing with samples of pure Dy they were even able to determine the actual quantity of Dy in the particular sample.

1.1 Principle and Definition of Radiochemical Neutron Activation Analysis

Although himself a chemist Hevesy never applied radiochemistry to any activated samples for analytical purposes; this was first done by Seaborg and Livingood, who determined Ga after the addition of carrier and radiochemical separation of iron activated at the Berkeley cyclotron.

RNAA is a method for the determination of elements, and its full power was not realized until after the second World War, when the availability of nuclear reactors was brought to the attention of the analytical community. A clear presentation of the principles of RNAA, including carrier addition and yield determination, was
first made by Boyd,(3) who still provides the fundamental description of what was later referred to as comprehensive RNAA:(4)

1. activation with neutrons
2. carrier addition
3. radiochemical separation
4. measurement of activity
5. determination of yield.

After half a century RNAA has reached maturity, the principles are well understood and no major technological developments are expected to take place in the foreseeable future. At the same time, it is also improbable that any other method will be found that could provide the same special characteristics so valuable for ascertaining the quality of trace element analysis.

1.2 Relationship to Instrumental Neutron Activation Analysis

The outstanding characteristic of neutron activation analysis in comparison with other methods of analysis is the timescale associated with the lifespan of the excited species or characteristic radionuclides, often referred to as indicators, which permit the introduction of a chemical separation between the end of activation and the beginning of measurement.

In purely instrumental neutron activation analysis this decay period is used only for simple physical operations, such as separating the sample from its container, taking an aliquot by volume or weight, cleaning the surface of the sample or adjusting its shape or volume before measurement is begun. In INAA the preservation of the integrity of the sample permits the determination of many elements in the same sample.

The radiochemical separation carried out during the decay period is characteristic of RNAA and serves to reduce or eliminate unwanted radionuclides interfering with the measurement of the indicator, so as to minimize the uncertainty associated with the determination of a particular element. RNAA is therefore basically a method for the determination of only a small number of elements in the same sample.

Over the years successful attempts have been made to reduce the need for radiochemical separations by advances in instrumentation for counting, supplemented with the use of γ-radiation or charged particles rather than neutrons for activation.(5) For highest accuracy at the lowest levels RNAA is still needed as a reference method.

1.3 Advantages and Limitations

RNAA is clearly not a nondestructive method, and at the same time the amount of work put into the analysis of each sample makes RNAA much more expensive than INAA. This is the cost that has to be paid for determining selected elements at much lower concentrations and superior accuracy in comparison with INAA, while maintaining most of the other excellent characteristics of this method, see Instrumental Neutron Activation Analysis, including the small self-shielding during irradiation with neutrons, which opens up the possibility of analyzing large samples as well without any pretreatment.(6)

Particularly for the lowest levels of trace elements RNAA provides several important advantages over alternative analytical methods:

1. absence of a reagent blank
2. corresponding insensitivity to contamination after activation
3. controlled addition of carrier to avoid losses by adsorption etc.
4. corresponding possibility of determining chemical yield or recovery.

The presence of a controlled amount of carrier during the radiochemical separation process, regardless of the original content in the sample, makes the a priori precision in the uncertainty budget independent of the concentration of the element to be determined, the determinand, see section 4.4. Any method that has been found to be useful for chemical separation of the indicator element from the material to be analyzed by any other analytical method, could also be used in RNAA. In this article we are therefore concerned only with the evaluation of the performance characteristics of the potential separation methods (see section 2.3) not with the methods themselves.

When carefully and thoughtfully carried out, RNAA qualifies as a so-called definitive method,(7) one of the reasons being its direct traceability to a comparator of the pure element to be determined.

2 THEORY AND OPERATING PRINCIPLES

The special features of RNAA can be expressed as a combination of separate, almost independent unit operations, and Figure 1(8) illustrates the entire process from the sample to be analyzed to the result of the analysis.

The RNAA sensitivity $S$ given in Equation (1) for a particular determinand element $X$ is expressed as the number of counts per unit weight of $X$, and it depends upon the half-life of its indicator $T_{1/2}$, the duration of the activation $t_a$, the decay time $t_c$, and the counting time $t_m$

$$S = \frac{C_x(1 - e^{-\lambda t_a}) e^{-\lambda t_c}(1 - e^{-\lambda t_m})}{\lambda}$$  (1)
Figure 1 Schematic representation of RNAA methodology.

where \( \lambda T_{1/2} = \ln 2 \), and the rate constant (Equation 2)

\[
C_x = P_i R_c P_m
\]

has to be determined experimentally from a known quantity of comparator.

The rate of formation \( P_i \) is proportional to the neutron flux density during activation, see section 2.2, but its magnitude varies by orders of magnitude from element to element. The recovery \( R_c \) and the detection efficiency \( P_m \) will be discussed later.

Table 1 lists those elements with corresponding indicators which have rate constants larger than that of Zn.\(^{9a}\)

### 2.1 Sample and Comparator

In RNAA the analytical sample is just as prone to contamination before activation, as it is in all other analytical methods. The characteristic insensitivity to contamination applies only after completion of the activation process, and it is therefore important that any conditioning or preprocessing of a sample be kept at an absolute minimum.

Some reactors require biological samples to be dried or lyophilized before activation in order to reduce formation of gases by radiolysis of the water content; this may, however, require special tracer studies to ascertain that no loss of determinand is incurred.\(^{10} \) At low levels of determinand any such preprocessing necessitates the introduction of a blank to be analyzed together with a sample in order to monitor possible contamination occurring before activation.

Although it is possible to carry out neutron activation analysis without activating an isotopic comparator together with the sample,\(^{9a}\) this is rarely done for RNAA. The limited number of elements that can be determined in the same sample makes the use of individual comparators much more attractive, because of the greater freedom it gives with respect to both activation and counting conditions.

A comparator is prepared from a weighed quantity of the element to be determined or a compound with an accurately known stoichiometry.\(^{11} \) chosen so that no other significant activity will be present at the time of measurement.

</table>
The validity of the comparator requires that it be activated under exactly the same conditions as the sample with respect to both time and space. It must be physically as similar as possible to the sample at the time of counting, i.e., after completion of the radiochemical separation: same counting vial, same volume, similar matrix, etc. However, the comparator should not be processed, in order to eliminate any possible risk of loss, which means that \( R_c \equiv 1 \), and the rate constant for the comparator \( C^*_c \) is reduced to Equation (3)

\[
C^*_c = P_c P_m
\]  

The comparator need not be identical or even similar to the sample, as long as it is exposed to the samefluence of neutrons. The sample, therefore, can be of any size or shape from up to perhaps several kilograms\(^{12}\) to practically weightless quantities, still using the same comparator. In some cases it may be appropriate to weigh the analytical sample, as well as to take an aliquot of the comparator after completion of the activation.

### 2.2 The Activation Process

Activation of a sample by neutrons could be carried out with a number of devices, such as accelerators, cyclotrons, radioactive sources\(^{13}\) or even spallation sources; nuclear reactors remain, however, the most suitable source of neutrons for RNAA.

Research reactors are found in many countries\(^ {14}\) and most of them offer irradiation services for neutron activation analysis with neutron flux densities up to \(10^{14} \) neutrons \(cm^{-2} \cdot s^{-1} \), which is more than sufficient for the determination of the elements listed in Table 1. More important is the spatial flux homogeneity that is needed to ascertain that samples and comparator irradiated together are exposed to exactly the same number of neutrons.

Irradiation of an element with a relative atomic mass \( A_i \) at a constant neutron flux density \( \varphi \) for a period of time \( t \), produces a specific activity of:

\[
\frac{N_A \sigma_A \varphi (1 - e^{-\lambda t})}{A_i} \text{Bq g}^{-1}
\]

where \( \sigma_A \) is the appropriate cross-section of the element for the formation of a specific radionuclide, and \( N_A \) is the Avogadro number.

The saturation activity achieved after an infinite irradiation time is numerically equal to the rate of formation of the indicator nuclide (Equation 4)

\[
P_i = \frac{N_A \sigma_A \varphi}{A_i}
\]

Some small reactors with modest neutron flux densities like the Canadian Slowpoke type\(^ {15}\) may be so stable in time that sample and comparator need not even be irradiated simultaneously. In most nuclear reactors, however, changes in neutron flux exposure during irradiation may take place as a result of the introduction or removal of other samples, movement of control rods, change of power level, moderator temperature, or virtually intermittent operation, as well as many other things beyond the control of the analyst. These changes will affect indicator isotopes differently because of their different half-lives; however, the simultaneous irradiation of a comparator of the element to be determined, the determinand, will automatically account for such changes.

Subject to the needed sensitivity the duration of irradiation should be kept as short as possible\(^ {9b}\) in order to:

1. keep the total activity of the sample low enough for proper handling without excessive shielding and time-consuming use of remote handling equipment;
2. minimize radiation decomposition of the sample, which may result in the loss of halogens, mercury\(^{16}\), or other elements, when the irradiation capsule is opened;
3. reduce the influence of long-lived activated matrix components on the choice of counting conditions;
4. limit the nuclear interference from double neutron capture in some elements\(^ {17}\).

### 2.3 Radiochemical Separation

During the period between the end of activation and the beginning of measurement the analytical sample is subjected to a radiochemical separation, which should be completed preferably within one mean life of the indicator.\(^ {9b}\) The performance characteristics of the radiochemical separation therefore must include the time needed to complete the task, which in practice limits the use of RNAA to elements with indicator half-lives in excess of a few minutes.

Sample decomposition in RNAA presents the same problems as in all other methods of chemical analysis\(^ {18}\) to ascertain carrier equilibration the procedure should include a complete oxidation–reduction cycle. The process can hardly be completed in less than several minutes, which is just feasible for V in human serum with an indicator half-life of 3.8 min\(^ {19}\), but barely enough for Al with 2.2 min half-life\(^ {20}\).

The absorption of a neutron gives rise to the emission of one or more capture \( \gamma \)-rays with energies of several MeV, which causes a nuclear recoil energy of \( 536 \times E^2_n/A_i \) eV which is enough to break a chemical bond. Because of this Szilard–Chalmers effect the activated atom no longer retains its original position in a chemical entity, and RNAA is therefore incapable of determining any speciation of an element. By
the same token, however, postirradiation carrier equilibrium does not necessarily require complete sample decomposition, but only complete dissolution. This is an important difference from other reference methods, such as isotope dilution mass spectrometry (IDMS), that rely on complete isotopic exchange between an added isotopic tracer and the total content of an element in the sample.

The addition of carrier is required not only for all elements that need to be determined, or rather their indicators, but also for some interfering elements, from which a good separation is important. Such a *hold-back carrier* could prevent adsorption or coprecipitation that might result in poor and irreproducible separation from interfering radionuclides.

The aim of a radiochemical separation is to achieve a high and reproducible recovery of the indicator radionuclide at the same time as a very low yield of all other radionuclides. The efficiency of the separation is expressed by the *separation factor*, \( K \), which, as shown in Equation (5), is the ratio between the yield of the interfering species, \( r_i \), and the recovery of the determinand

\[
K = \frac{r_i}{R_c}
\]

\( K \) is usually determined by adding a suitable radioactive tracer together with carriers to an unirradiated sample which is then processed and measured exactly as a normal sample.\(^{(22)}\) Experimentally determined separation factors are presented in Table 2\(^{(9c)}\) for a simple radiochemical separation of Cu in biological materials. A good separation will have separation factors better than \(10^{-3}\), but in extreme cases a separation factor better than \(10^{-7}\) has been demonstrated.\(^{(58)}\) It is worth pointing out that the use of highly effective radiochemical separations with good separation factors makes possible the determination of several other elements with less sensitivity than those listed in Table 1, such as Cr, Fe, Mo, and Cd.\(^{(22,23)}\)

Complete separation of the indicator from all other radionuclides in the activated sample is required when the indicator has to be measured by its emission of \(\beta\)-particles in order to achieve sufficient sensitivity.\(^{(24)}\) In most cases of \(\gamma\)-emitting indicators a high separation factor is needed only for the dominant interfering elements. Such *interference removal* is often needed for activated matrix components such as \(^{24}\)Na, \(^{42}\)K, and \(^{82}\)Br that dominate the \(\gamma\)-spectra of activated biological samples for days or weeks after the end of irradiation. Successful removal of \(^{24}\)Na is possible by means of hydrated antimony pentoxide,\(^{(25)}\) and other matrix indicators may be removed by precipitation with thioacetamide, extraction of Fe with ether, or other conventional methods of chemical separation.\(^{(26)}\) It should be recalled that nuclear interference from matrix elements cannot be eliminated by a radiochemical separation, but requires a preirradiation separation.

Each combination of determinand element and matrix composition may have its own optimum radiochemical separation method that minimizes the effort and maximizes the quality of the final result. A general discussion of the factors involved in such an optimization must be based on the separation factors needed for the particular analytical task. This paves the way for the use of less specific *group separations*, the use of *scavengers* to collect the elements to be determined, adsorption on solid oxides, activated carbon etc. Some of these methods seem to work best without carrier addition, but without determination of the recovery of the indicator these methods would suffer from an intrinsic lack of credibility.

### 2.4 Methodology of Counting

A radiochemically separated sample that contains only the indicator radionuclide could be measured by any suitable instrument with a sufficiently high detection efficiency, and in this respect it would be hard to beat a simple Geiger-Müller (GM) counter or liquid scintillation counter which detects \(\beta\)-particles with close

to 100% efficiency. It is, however, possible only in very special cases to prove that the sample does not contain any other radionuclides that might influence the measurement. In other cases the required high radionuclidic purity may be achieved only at the cost of a lower recovery of the indicator.

Most radiochemically separated samples therefore contain other radionuclides than the indicator and therefore must be measured with instruments that can distinguish between the radionuclides present, usually by measurement of a complete γ-spectrum, where individual radionuclides can be identified by their different γ-energies.

Among such detectors the Na(Tl) scintillation detector is available in the largest sizes, which may even be used to surround the sample; it therefore offers the highest detection efficiency, $P_m$. Better γ-energy resolution is obtained with the germanium semiconductor detector, which will reduce interference from accompanying radionuclides, but in return carries a higher cost and a lower efficiency.

From the point of view of minimum interference the optimum decay time, from end of activation to measurement is given by Equation (6)

$$t_c = \frac{1}{\lambda} - t_i$$

where the indicator is closer to saturation than any of the other radionuclides.

The optimum choice of peak boundaries for peak area evaluation depends upon the full width at half-maximum (FWHM) and the relative height of the photo peak to the base continuum. The optimum half-width has a limiting value of 0.90758 FWHM for photo peak heights approaching zero, and Figure 2 shows optimum half-widths for peak area integration as a function of relative peak heights and FWHM.

The FWm is a function of $\gamma$-energy $E$

$$\text{(FWHM)}^2 = wE + w_0$$

where the coefficients $w$ and $w_0$ in Equation (7) are determined from the actual spectrum by weighted linear regression of FWHM$^2$ for the largest photo peaks on their corresponding $\gamma$-energies or channel numbers. These peaks would be the same as used for energy calibration by simple linear regression of $\gamma$-energies on channel numbers and do not necessarily include any photo peak of the indicator nuclide.

The FWHM corresponding to the chosen photo peak of the indicator is now used in combination with Figure 2 to select the peak boundaries for optimum precision of the partial peak area evaluation according to Covell. The partial peak area is then converted to the full peak area by assuming a Gaussian shape with the assumed FWHM, which is a purely mathematical operation that does not change the relative precision of the measurement. The final result of the data processing is the full peak area in counts together with its associated standard deviation, calculated on the basis of a Poisson distribution for each individual channel content. An implementation of this approach has been verified by comparison with IAEA (International Atomic Energy Agency) test spectra with
known peak areas, as well as with actual spectra with known ratios.\(^{28}\)

The possible interference from other radionuclides is not estimated by attempting to resolve doublets or multiplets, but by the measurement of the effective values \(f\) of potentially interfering elements.\(^{30}\) By irradiating a known quantity of an interfering element exactly like a sample together with a comparator of the determinand, and using the peak boundaries for the determinand, the effective value is determined as the ratio between counts per unit mass of interfering element relative to determinand. For elements with effective values in excess of 0.01 separation factors should be determined in order to specify the assumptions of the RNAA.

Table 2 lists effective values for seven elements suspected of interfering with the determination of Cu by RNAA.\(^{9c}\) This allows the user to judge the performance characteristics of the method for the analysis of actual samples.

Interference from the formation of the indicator nuclide during activation from another element by \((n,p)\), \((n,\alpha)\) reactions, or by double neutron capture, is usually referred to as nuclear interference and can be corrected for only by the simultaneous activation of an additional comparator of the interfering element.\(^{17}\) A particularly treacherous interference occurs when the indicator nuclide is also produced by fission of uranium, which may necessitate a separate determination of this element\(^{31}\) in order to correct for this positive bias.

Sometimes the absence of interference may be demonstrated by the determination of the same element using two different indicator nuclides.\(^{32}\)

### 2.6 Recovery Correction

The determination of recovery or chemical yield of the analytical separation is an outstanding property of RNAA and enables the method to estimate the true content of the determinand in the sample.

In routine applications of highly standardized radiochemical separations the chemical yields are often determined by adding radioactive tracers of the determinands.

---

**Figure 2** Optimum half-width of Gaussian peak fraction for peak area evaluation by the method of Covell as a function of height of linear continuum under the peak for selected values of FWHM. (Reprinted with permission from K. Heydorn, W. Lada, *Anal. Chem.*, 44, 2314.\(^{29}\) Copyright 1972, American Chemical Society.)
to an inactive sample before performing the separation, exactly as described for the determination of interferences. The use of such a priori chemical yields instead of individual recoveries is justified only when the yields are close to 100% and the correction therefore quite small.\(^{(33)}\)

In research applications, where every analysis might differ from the rest, recovery is usually not quantitative and is susceptible to considerable variation from sample to sample, which means that recoveries must be determined for each individual analysis. In that case much larger corrections for chemical yield can be accepted, while still maintaining statistical control.

A comparison of the amount of carrier in the separated sample with the originally added quantity by almost any analytical method could be used for the determination of recovery, and in many applications gravimetry has been used. However, such chemical methods might jeopardize the principle of not processing the added carrier reference comparator sample, and therefore a direct instrumental method without any additional treatment and a minimum of handling of the separated sample is clearly preferable, and simple radioanalytical methods based on either a short re-irradiation or the addition of a radioactive tracer, are often the methods of choice:

1. With carrier added at the milligram level the irradiation time can be very short, and the measurement of the induced radioactivity can be very simple.\(^{(34)}\) By simultaneous irradiation and direct comparison between added and recovered carrier there is no need to know the amount of carrier accurately, provided the content in the sample is negligible in comparison to the added quantity of carrier.

2. Addition of a radioactive tracer together with the carrier opens the possibility of determining recovery at the same time as measurement of the indicator. Clearly, the tracer should not be produced by neutron activation and the amount added should be chosen carefully in order not to disturb the measurement.\(^{(35)}\) A list of radionuclides used as tracers for the determination of individual recoveries of added carrier is presented in Table 3. If they are truly carrier-free they may even be added to the sample before activation, so that any losses that might occur as a result of preirradiation processing would be included in the recovery.\(^{(10)}\)

3. Instead of adding the radioactive tracer to the sample before separation it may be added after completion of the separation and the measurement of the indicator, in order not to cause spectral interference. It is now possible to correct for recovery during separation by comparing the specific activities of the carriers added to the separated sample and the carrier reference comparator sample by using substoichiometric methods.\(^{(36)}\)

It has been proposed that an internal standard of another element be used to correct for recovery;\(^{(37)}\) however, this is limited to the cases where this element yields a radionuclide isotopic with the indicator nuclide.

If carefully thought out, the individual determination of recovery for each sample requires very little additional effort in comparison to the radiochemical separation.\(^{(37)}\)

### 2.7 Final Calculation of Analytical Result

The calculation of results obtained by RNAA is basically similar to that of INAA; however, the proper utilization of the various measurements for correcting initial results and estimating their uncertainty may become quite complicated. It is, therefore, strongly recommended that

</table>
calculation be done in the form of a spread-sheet, not only in order to avoid making mistakes, but also because it facilitates the implementation of quality control, as well as the smooth propagation of errors from one stage to the next.

As an example let us pretend that we have carried out RNAA for two determinands in the same sample, and for simplicity let us assume that both can be determined from the same γ-spectrum, but with some interference from one indicator to the other. We also assume that comparators of both determinands were irradiated together with the sample. The data available for calculating the concentration of determinands in a sample may be organized as shown in Table 4.

Calculations are now carried out in the following sequence:

1. Photopeak counts are corrected to count rates at the time of pile-out by multiplication with a decay correction for

\[ t_c = \text{date and time of counting} \]
\[ - \text{date and time of pile-out} \]
\[ \text{decay correction} = \frac{\lambda e^{t_c}}{1 - e^{-\lambda t_c}} \quad (8) \]

In Equation (8) \( \lambda \) is the decay constant for the radionuclide associated with the photopeak in question.

Decay corrections are conveniently placed in the columns immediately after the counting data:

<table>
<thead>
<tr>
<th>Columns</th>
</tr>
</thead>
<tbody>
<tr>
<td>Sample</td>
</tr>
<tr>
<td>Comparator</td>
</tr>
<tr>
<td>Comparator</td>
</tr>
</tbody>
</table>

2. The uncorrected content of 1 determinand in the separated sample and its corresponding standard deviation are calculated as:

\[ \text{content} = AD \times \frac{M}{AM} \times \frac{O}{AO} \]
and placed in column CA

\[ CV^2 = \left( \frac{N}{M} \right)^2 + \left( \frac{AN}{AM} \right)^2 \]

standard deviation = \( \sqrt{CV^2} \times \text{content} \)
and placed in column CB

3. The uncorrected content of 2 determinand in the separated sample and its corresponding standard deviation are calculated as:

\[ \text{content} = BD \times \frac{Q}{BQ} \times \frac{S}{BS} \]
and placed in column CC

\[ CV^2 = \left( \frac{R}{Q} \right)^2 + \left( \frac{BR}{BQ} \right)^2 \]

standard deviation = \( \sqrt{CV^2} \times \text{content} \)
and placed in column CD

4. Correction of the influence of 2 determinand on the result for the 1 determinand requires the calculation of the effective value:

\[ \text{effective value} = \frac{AD \times BM}{BD} \times \frac{BO}{AM} \times \frac{AO}{AO} \]
and placed in column CE

\[ CV^2 = \left( \frac{AN}{AM} \right)^2 + \left( \frac{BN}{BM} \right)^2 \]

standard deviation = \( \sqrt{CV^2} \times \text{effective value} \)
and placed in column CF

5. The corrected content of the 1 determinand in the separated sample is now calculated as:
\[
\text{content} = \frac{\text{CA} - \text{CC} \times \text{CE}}{\text{D}} \text{ is placed in column CK}
\]
and placed in column CH

At this stage it should be checked whether CG is negligible in comparison with the quantity of added carrier; if not the recovery E should be reduced by subtracting their ratio.

6. The real concentration of determinand in the sample material and its uncertainty are finally calculated from the original sample weight and the recovery of the appropriate carrier in the separated sample:
\[
\text{concentration} = \frac{\text{CG}}{\text{D} \times \text{E}}
\]
\[
\text{CV}^2 = \left( \frac{\text{F}}{\text{E}} \right)^2 + \left( \frac{\text{CH}}{\text{CG}} \right)^2
\]
standard deviation = \text{SQRT(CV}^2 \times \text{ABS(CK)}

and placed in column CL

An example of actual results obtained from the determination of Pt in a reference material from the Bureau Communautaire de Référence (BCR) certified reference material (CRM) 186 pig kidney\(^{(38)}\) is shown in Table 5, which also indicates the spreadsheet columns, from which these results are taken. The indicator for Pt is \(^{199}\text{Au}\), formed by the decay of \(^{199}\text{Pt}\), but also from neutron capture in \(^{198}\text{Au}\), the indicator for gold. The correction for nuclear interference is in this case comparable to the total amount of \(^{199}\text{Au}\) and therefore leads to very large relative uncertainties in the final results for Pt.

Corrections for nuclear interference from uranium in the determination of La, Ce, Sm, Nd, Zr, Mo, Ru, Te, etc. may be carried out in a similar way,\(^{(9)}\) except that the concentration of U in the sample has to be determined separately.

This paradigm can easily be modified to accommodate other situations in RNAA with additional determinands and \(\gamma\)-spectra, using the same general approach to calculation of results and their uncertainties.

Corrections for possible blank values, such as those associated with preirradiation treatment of the sample,\(^{(33)}\) must be carried out by calculating the blank value exactly as if it were a sample and then subtracting from the final result for the sample itself.

3 INSTRUMENTATION

Radiochemical separation requires a radioanalytical laboratory of Type C,\(^{(39)}\) which is essentially just a good quality chemical laboratory with a radiochemical hood and a little shielding to reduce radiation exposure.

Requirements for irradiation facilities and counting equipment do not go beyond those needed for INAA, but the emphasis on some of the features and specifications is shifted because of the nature of the separated sample and the low levels of activity of the indicator nuclides.

3.1 Irradiation Systems

In order to benefit most from the properties of RNAA it should be possible to activate rather large samples without any preceding treatment that might lead to losses or contamination. As with INAA it is important that the entire sample and associated comparators be exposed to identical neutron flux densities for exactly the same time.

This is best achieved in a system that permits rapid transport in and out of the irradiation zone, while providing rotation of the irradiation container during activation.\(^{(40)}\) In order to minimize sample decomposition

Table 5 Determination of the platinum content in BCR CRM 186 pig kidney by RNAA\(^{(38)}\)
the thermal neutrons should be accompanied by a minimum of epithermal and fast neutrons, as well as $\gamma$-radiation.

In Figure 3 is shown a drawing of such a facility in the Danish Reactor DR 3, which permits simultaneous irradiation of three containers of about 30 cm$^3$, while they are rotated in a thermal neutron flux density of $3 \times 10^{13}$ neutrons cm$^{-2}$s$^{-1}$ shielded by 50 mm of bismuth to reduce the $\gamma$-ray intensity.

### 3.2 Counting Equipment

A complete radiochemical separation of the indicator nuclide would allow use of the very sensitive but nonspecific detection of $\beta$-particles by very simple counting equipment. However, no separation is perfect, and in practice the less sensitive, but high-resolution detection of $\gamma$-rays is preferable, wherever possible.

With the availability of germanium semiconductor detectors having efficiencies comparable to, or even surpassing, that of the $3'' \times 3''$ sodium-iodide scintillation detector, the instrumentation for RNAA becomes similar to that needed for INAA with the same electronic equipment and multichannel analyzer with at least 16 K ($K = 1024$) channels.

The detection efficiency $P_m$ determines the sensitivity of determination $S$, while an improved resolution of the detection system improves both the precision and accuracy of the determination by:

1. facilitating the detection of unexpected interferences
2. minimizing the correction for known spectral interferences
3. reducing the standard deviation of the photopeak area
4. improving the detection limit.

Similar improvements may sometimes be achieved by the use of two or more detectors in combination with coincidence/anticoincidence circuitry to obtain spectra providing improved detection limits with only a slight loss of sensitivity.$^{(41)}$

As previously discussed the close counting geometry of the separated sample must be exactly equal to that of the comparator, calling for an accurately reproducible counting position to ascertain exactly equal counting efficiency and coincidence losses for both. A counting assembly with such reproducible counting positions for liquid samples is shown in Figure 4.

The usually low activity of the separated samples makes corrections for dead time and pile-up less critical, and a simple 50–60 Hz pulser with a narrow peak in the highest channels of the spectrum is a reliable way of making such corrections. The use of digital signal processing (DSP) improves resolution at high count rates, but seems to give no particular advantages at low count rates.

### 4 QUALITY ASSURANCE

While RNAA is potentially capable of providing analytical results without bias and with known uncertainty, the method clearly requires no less skill and experience than other methods. Quality assurance is therefore a sine qua non, and fortunately the method is particularly well suited for modern methods of quality control/quality assurance (QC/QA) based on the so-called BIPM (Bureau International des Poids et Mesures) philosophy.$^{(42)}$
The implementation of this line of thought is described in a basic ISO (International Organization for Standardization) document,\(^{(43)}\) and for use in analytical chemistry in a Eurachem Guide;\(^{(44)}\) none of these documents, however, provide any guidance with respect to RNAA or to activation analysis in general.

### 4.1 Statistical Control

The analytical method is in a state of statistical control when its known sources of variation fully account for the observed variability among replicate determinations.

The \textit{a posteriori} variability of \(n\) replicate analyses is expressed as the variance \(s^2\) of results \(y_i\) in Equation (9)

\[
s^2 = \frac{\sum (y_i - y_0)^2}{n - 1} \tag{9}
\]

where \(y_0\) is their mean value.

When the analytical method is completely defined, it is possible to identify and evaluate all sources of variation by statistical or other methods, referred to as uncertainty components of type A or B.\(^{(43)}\) Their influence on the analytical results is calculated by the law of error propagation on the basis of variances \(\hat{\sigma}^2\) of \(p\) individual components \(x_i\) (Equation 10)

\[
\hat{\sigma}_0^2 = \sum_{i=1}^{p} \left( \frac{\partial y}{\partial x_i} \right)^2 \hat{\sigma}_i^2 \tag{10}
\]

This resulting variability may be calculated without actually carrying out any analyses and is therefore referred to as the \textit{a priori precision}.\(^{(45)}\)

In RNAA and other methods where the process of counting stochastic events is part of the analytical method the statistics of counting has to be compounded with the \textit{a priori precision}, even though its contribution is not known until an actual measurement has been carried out. The calculation of \textit{counting statistics} is based on the Poisson distribution for the number of counts detected from a radioactive source, and this assumption has been amply demonstrated to be fulfilled in neutron activation analysis. Each photopeak area is associated with a standard
deviation, \( \sigma_C \), calculated from the same spectrum and by the same computer program. The total expected a priori variability of radioanalytical results then becomes Equation (11)

\[
\tilde{\sigma}^2 = \tilde{\sigma}_b^2 + \sigma_C^2
\]

(11)

where \( \sigma_C^2 \) expresses the contribution from counting statistics.

Agreement between a priori and a posteriori variability means that the analytical method is in a state of statistical control; this is tested by calculating the statistic \( T \) by Equation (12)

\[
T = \sum_{i=1}^{n} \frac{(y_i - \tilde{\mu})^2}{\tilde{\sigma}_i^2}
\]

(12)

where \( \tilde{\mu} \) is calculated by Equation (13)

\[
\tilde{\mu} = \frac{\sum_{i=1}^{n} y_i \tilde{\sigma}_i^{-2}}{\sum_{i=1}^{n} \tilde{\sigma}_i^{-2}}
\]

(13)

as the weighted mean of \( n \) observations. If there is no significant difference between the expected—a priori—and the actual—a posteriori—standard deviations the statistic \( T \) is closely approximated by a \( \chi^2 \)-distribution with \( n - 1 \) degrees of freedom.

\( \chi^2 \)-distributions from this distribution show that there is a disagreement between the sources of variability expected to influence the result according to Equation (11) and the observed variability. The process of identifying the sources and magnitudes of variability that influence the actual analytical results is called the Analysis of Precision.

### 4.2 Verification Methods

Verification means to verify the absence of errors, and the analysis of precision is an important tool for ascertaining the absence of unknown sources of variability. It is also possible to use this statistic to demonstrate the absence of systematic errors.

The most important condition for relying on the analysis of precision is that the standard deviations \( \sigma_i \) of the analytical results are correctly estimated for each individual measurement. Hence, it must be ascertained that the program used to calculate the results and its associated uncertainty correctly takes into account the contributions from counting statistics and other known uncertainty components. This was tested by a series of experiments involving replicate activation and counting of identical samples under a variety of conditions, covering the entire field of potential application.

* SEM = Standard error of the mean = Standard deviation/\( \sqrt{n} \).

As an example it was considered necessary to ascertain that counting statistics were correctly calculated for spectra recorded with different gains, which means that identical photopeaks had different widths expressed as FWHM. By counting the same \(^{152}\)Eu source up to 30 times at different gain settings and using the most intense \( \gamma \)-line at 122 keV as a comparator the results shown in Table 6 were obtained. For each set of photopeak areas and associated counting statistics, \( \sigma_C \), the statistic \( T \) was calculated in accordance with Equations (12) and (13). All photopeak areas covering an intensity range of two orders of magnitude and values of FWHM from 2.8 to 15 channels were found to be in good statistical control with the possible exception of the 344 keV photopeak. This photopeak offers the highest precision next to the comparator peak and is therefore providing the highest sensitivity for the detection of unexpected sources of variability; however, no correlation with FWHM could be observed and it was therefore concluded that, although there might be a small additional random source of variation, there was no systematic effect associated with the changes in photopeak width.

Once it has been verified that all known sources of variation are correctly accounted for in the calculated standard uncertainty of the analytical result, it becomes possible to detect and identify unknown sources of variability by judicious use of the analysis of precision. Verification of the absence of unknown sources of variability in the analytical results, however, does not exclude the presence of a constant bias or proportional error. Only comparison with results obtained by independent methods or the analysis of materials with known composition can be used for such verification.

The preferred way of verifying the absence of such errors is to analyze a series of matrix-matched reference materials with certified concentrations of the determinand for the entire range of concentrations of interest. Results of such a verification analysis for selenium by INAA and RNAA are shown in Table 7 giving results for seven biological reference materials certified by BCR and covering a concentration range of more than two decades. On the assumption that the confidence intervals for the certified values represent the standard uncertainty with a coverage factor $k = 2$, we can combine the uncertainties with the standard uncertainties for the actual results. The ratios between the observed and the expected results are calculated together with their associated standard deviations and presented in the last column of Table 7.

The weighted mean of these ratios is calculated according to Equation (13) and the distribution of the results is tested by the $T$-test from Equation (12). In this case, the test shows no disagreement with the expected ratio of one, and therefore no detectable systematic error. Within the range of concentrations and matrices investigated we can therefore disregard blank or contamination problems, as well as interference or calibration errors.

### 4.3 Traceability Chain

Traceability is characterized by an unbroken chain of comparisons that relates the analytical result to a national or international realization of the appropriate SI units. Each step of the traceability chain must be associated with an expression of uncertainty in accordance with the ISO document, so that the combined uncertainty of the analytical result can take this into account.

Traceability is not so difficult to establish in the physical measurement of a property of a particular sample, including elemental analysis by INAA. Traceability in chemical analysis is much more complicated for two reasons:

- The traceability chain is broken as soon as a chemical separation takes its beginning, i.e. already at the sample dissolution stage.
- There are a huge number of chemical species that may require determination, some being unavailable in pure condition.

In this respect RNAA is superior to other analytical methods in keeping the traceability chain unbroken because:

- carrier addition and equilibration take place right from the dissolution stage, thereby restoring the traceability chain by the determination of the recovery of added carrier;
- the number of elements that can be determined by RNAA is not more than approximately 70; the majority of these can be used directly as comparators in the form of pure elements or compounds with known stoichiometry.

It must, however, be remembered that RNAA determines a particular isotope of the element to be determined and therefore relates directly only to the same isotope in the comparator. Thus, the indicator radionuclide represents the element as such only if the isotopic composition of the comparator exactly equals that in the sample. For the most sensitive elements listed in Table 1 this condition is essentially always fulfilled; but in special cases the isotopic traceability becomes of major concern.

Neutron activation analysis was for example used for the determination of the specific activity of $^{125}$I and $^{129}$I using $^{126}$I, $^{128}$I, and $^{130}$I as indicators. In this case total iodine content had a completely different isotopic composition from naturally occurring iodine and could
only be determined by using individual comparators for all nuclides, each having its own traceability chain.

The uncertainty with which a result can be reported is thus limited by the uncertainty of the traceability chain, which should therefore be kept at a level where its contribution is small in comparison with other uncertainty components. This is usually achieved by the use of certified reference materials from internationally recognized sources like BCR or NIST (National Institute of Standards and Technology).

In a method like RNAA with inherently small uncertainties and a short traceability chain the contribution to the uncertainty from the traceability chain can be kept at a level of less than 1% when several different pure isotopic comparators are used.\(^{52}\) The use of the so-called \(k_0\) method\(^{53}\) based on the use of comparators of elements different from the determinand also represents a break in the traceability chain and is therefore discouraged in the context of using RNAA for certification purposes.

### 4.4 Uncertainty Budget

When standard deviations, \(\sigma_i\), have been estimated for all uncertainty components, \(p\), discussed in section 2, the uncertainty budget is composed simply by listing the individual items of the summation in Equation (10). Common to all RNAA budgets are sample weight, quantity of comparator, half-life of indicator, neutron flux density variation, measurements of decay and counting times, amount of carrier, and recovery. Another important common feature is that the radiochemical separation as such does not contribute to the uncertainty in any other way than expressed by the recovery, which means that the entire a priori standard uncertainty is independent of the concentration of the determinand.

All these major uncertainty components are evaluated by statistical methods and therefore belong to Type A.\(^{43}\) Other uncertainty components may have to be evaluated by inference from other methods or by previous experience; such contributions are referred to as Type B. In RNAA, uncertainty components of Type B might include several potential losses or gains of determinand or comparator that are not otherwise accounted for, such as

- sample contamination before or during irradiation
- loss of determinand before complete carrier equilibration
- leaching from or adsorption to the irradiation container walls
- influence of moisture etc. on sample weight
- effects of radiolysis
- incomplete sample dissolution.

Many of these uncertainty components apply to both sample and comparator, and estimated corrections should in principle be applied to the results of the analysis. The comparator should have a much higher concentration of determinand than the sample and therefore be much less susceptible to contamination than the sample, but losses might occur from

- incomplete transfer from the irradiation container
- diffusion, adsorption, or precipitation during irradiation.

The experienced analyst should be able to reduce the magnitude of all these effects to the extent that even with an estimated Type B combined standard uncertainty of 100% of the correction to be applied, there would be no significant influence on the uncertainty budget.

In a budget for the determination of chlorine by RNAA\(^{48}\) all Type A contributions are listed with their individual standard uncertainties, as shown in Table 8. Based on the analysis of precision and the application of the \(T\)-statistic from Equation (12) it had been concluded that no detectable contribution from Type B uncertainty components could be detected.

Since RNAA is characterized by the absence of reagent blanks the uncertainty budget contains only relative sources of variation, which facilitates the comparison of the items: it is here immediately recognized that the variation in fluence between sample and comparator is the main contributor to the combined uncertainty, whereas weighings have no detectable effect. The influence of half-life depends entirely on the time lapse between the measurement of the separated sample and the comparator. In this particular case the recovery is determined by re-irradiation, which means that the contributors from its measurement are exactly the same as for the sample itself.

Even in a complicated method like RNAA the combined uncertainty is almost always dominated by one or two uncertainty components, one of which is often the contribution from counting statistics. As pointed out above, this contribution is not known until an actual analysis has been carried out; therefore it does not strictly

belong to the a priori precision, but must of course be included in the combined uncertainty.

At very low levels of the determinand the a priori precision becomes insignificant, and the uncertainty is completely attributed to the counting statistics; this contribution can be influenced by the choice of detector, counting geometry and counting time, thereby making an a priori estimation less meaningful.

4.5 Statement of Uncertainty

Results presented without uncertainty are useless because no conclusions can be based on them; results with incorrect uncertainty are dangerous because false and misleading conclusions may be drawn.

The tradition of quoting only uncertainty from counting statistics when reporting results obtained by neutron activation analysis is therefore dangerous and should be supplemented with the a priori precision obtained from the uncertainty budget.

Both the analytical result and its uncertainty must be given in SI units with the appropriate subdivisions, and it is preferable to state the standard uncertainty, so that statistical tests and inferences can be made directly from the numbers presented. This applies to all results, including those that are not significantly different from zero, or even negative numbers.

As an example we shall take the numbers for platinum in radiochemically separated samples of BCR 186 that were presented in Table 4. These numbers are typical for analytical results, obtained as a difference between two almost equally large numbers: without any real difference between these numbers the probability of getting positive or negative results is the same, and getting three negative and one positive result from four experiments as in this case, has a probability of 25%. The quoted standard uncertainties confirm that the individual numbers are not significantly different from zero.

Thus, there is no reason to regard these numbers as in any way suspicious and therefore they should also be treated in exactly the same way as all other results. Concentrations are calculated exactly as usual, and results are presented in Table 9 together with their uncertainties.

Application of the T-test from Equation (12) shows no significant difference between the results, which can therefore be pooled in accordance with Equation (13). The final result is closer to zero than any of the individual results and its standard uncertainty is smaller.

The standard uncertainty provides a confidence interval corresponding to approximately 67% for a normal distribution and this changes very little with deviations from this distribution. However, in many practical situations this confidence interval is not generally appreciated, and it has been decided to multiply the standard uncertainty with a coverage factor, $k;^{(43)}$ which is frequently taken to be a factor of 2. This gives a coverage of 95% for a normal distribution, but this number may change considerably with deviations from this assumption. Under all circumstances the coverage factor must be reported for all analytical results, so that standard uncertainties can be recalculated before use of the data.

Instead of reporting negative results or results with large uncertainties some laboratories prefer to present their results simply as n.d. (not detected). In other cases, compliance with legal requirements or limits necessitates reporting safe upper limits, which are conventionally set as three times the standard uncertainty. Such deflation of the information content is, however, strongly discouraged and should always be accompanied by the reporting of the original data, positive or negative, with their associated standard uncertainty.

Proper reporting of analytical results makes possible the direct application of the analysis of precision and other statistical tools to help in deciding whether a difference between sets of measurement has been observed or not and thereby helps to avoid drawing false conclusions.

5 PERSPECTIVE AND FUTURE DEVELOPMENTS

A top priority in the analytical perspective is the introduction of the BIPM philosophy$^{(42)}$ in analytical chemistry courses at the university level and the implementation of the corresponding ISO Norm$^{(43)}$ at the practical level, so that analytical results can assume their rightful place in the hierarchy of measurement science. This process has been hindered by the traditionally inexact and ambiguous chemical terminology,$^{(54)}$ and the pontification of incommensurate terms and concepts in some ISO standards.$^{(55)}$

Publication of the EURACHEM guide$^{(44)}$ has been a
very significant step forward, but its recommendations are not yet mandatory even for laboratories seeking accreditation. The methodology of RNAA has contributed significantly to revealing such inadequacies and continues to pioneer the introduction of generally recognized measurement concepts and definitions in analytical chemistry.

5.1 Analytical Metrology
The purpose of analytical metrology is the introduction and implementation of metrology in analysis, based on the successful use of the BIPM philosophy in physical measurements, which at any rate are assuming a dominant position in contemporary analysis. In metrology we require correction for all known errors before reporting a measurement, while the uncertainty of the correction must be included in the uncertainty budget. This is often neglected in analytical measurement, where even corrections for blank value or recovery are not always made.

This has been brought out very clearly by comparisons between traditional chemical analyses and purely instrumental methods, where the latter frequently yields higher results for the content of trace elements or other determinands, because of incomplete dissolution of the sample or loss of elements. At the lowest levels this has sometimes been compensated by the inadvertent contamination of the sample during chemical processing or inadequate blank correction.

Correction for incomplete recovery that can always be made in RNAA by measurement of the chemical yield of the carrier is much less straightforward in alternative methods, but nevertheless has to be done during the development stage of the analytical method by using radioactive or stable tracers.

Correction for incomplete sample dissolution can be made by separate analysis of the solid residue by an instrumental method such as INAA.

If such corrections are small their contribution to the uncertainty budget is also small and may be based on sound judgement as a Type B component to the combined uncertainty.

5.2 Certification Analysis
The certification of reference materials for elemental content is required for purposes of international traceability and the mutual recognition of laboratory accreditation needed in environmental and commercial activities. No effort is spared by the leading suppliers of CRMs to make sure that the certified concentrations are reliable, and each of them have developed procedures for performing certification analyses that minimize the risk of erroneous or misleading certification.

The aim is to certify the total amount of an element present in the material, regardless of its chemical or physical form, and the certified value should be as close as possible to the true value, which means that corrections must be made for all known or assumed biases. In order to minimize the risk of overlooking unknown or unexpected biases, the use of several independent analytical methods for determining the same element is the basis for all serious certifications.

The absence of a reagent blank, the possibility of determining the recovery of added carrier, and the maintenance of statistical control make neutron activation analysis very attractive for the certification of low concentrations of the elements listed in Table 1. Together with its direct traceability to the pure element this makes neutron activation analysis a potentially definitive method.

The combination of RNAA with INAA using different indicators and different comparators even opens up the possibility of self-validation by fulfilling most of the requirements for completely independent methods of analysis. This introduces the possibility of certifying reference materials for elements for which no alternative reliable methods are available.

These properties of RNAA further emphasize the applicability of this method for certification purposes, and Table 10 presents examples of elements determined in a variety of reference materials, certified by BCR and covering the entire range of trace element concentrations from 0.01 mg kg\(^{-1}\) to 0.01%. Particularly since the introduction of natural materials for certification, NIST and all other major suppliers have counted on neutron activation analysis not only for elements with

high sensitivity, but also for elements where alternative methods are not entirely satisfactory; this situation is not likely to change in the foreseeable future.

5.3 Sampling Constants

The characterization of a natural CRM must include information about possible heterogeneity, either in the form of a minimum sample size or – preferably – as a statement of the maximum sampling constant. All reference materials are carefully homogenized during their preparation, which means that they may be considered uniform and therefore can be characterized by the Ingamells’ sampling constant (Equation 14)

\[ K_S = R^2 W \]  

where \( R \) is the coefficient of variation observed by the analysis of replicate samples with weight \( W \). With a known sampling constant the contribution of heterogeneity to the variability of results is accounted for by adding a term to the a priori precision from Equation (11) (Equation 15)

\[ \sigma^2_w = \sigma^2 + \frac{K_S^2}{10^4 W} \]

which also shows that the sampling constant can be determined by analyzing a number of samples by an analytical method in statistical control.

Present reference materials have sampling constants of the order of 1 g, but modern methods of analysis use much smaller samples and therefore need materials with smaller sampling constants. Sampling constants need to be determined separately for each determinand, and the use of methods that are in statistical control regardless of sample size is therefore in great demand. For many elements both RNAA and INAA can be used on samples in the milligram to microgram range without problems and therefore can be used to advantage in future verification of very small sampling constants just by activating the samples in very high neutron flux densities.

27. E. Damsgaard, K. Heydorn, ‘Synthesis of Precision for the Certification of Phosphorus in Biological Materials by

Radiochemical activation analysis is a more laborious analytical method than instrumental analysis, but can be used to determine elements at lower concentrations. In most cases, the sample to be analyzed is separated into groups of elements rather than individual elements, so that the elements do not interfere with one another during the measurement of radionuclides content. Schemes for separation into multielement groups are given for metals, biological, geological and environmental samples.

1 INTRODUCTION

While instrumental neutron activation analysis (INAA) is more popular than RNAA (radiochemical neutron activation analysis), owing to its simplicity, RNAA can determine much lower concentrations than INAA, because the interferences from other radionuclides are reduced considerably. Whereas INAA involves only activation and activity measurement, RNAA also includes dissolution of the sample and chemical separation of the sample solution. In some cases, the interferences can be removed by decay (“cooling”) and INAA can be used. However, in many cases the IRNs (indicator radionuclides) are shorter lived than those of the interferences, and in other cases the required decay time is too long to be practical. Owing to the chemical dissolution, separation and recovery yield determination, RNAA involves more person hours and should be avoided when it is possible. Heydorn, in his article (Radiochemical Neutron Activation Analysis), shows why RNAA is so important in verification of the concentration of trace elements in reference materials. However, RNAA is not just used for validation of reference materials, although this is clearly one of its main uses. RNAA involves irradiation and counting, dealt with in the article Instrumental Neutron Activation Analysis, as well as dissolution of the samples and separation of the dissolved samples into various groups. The dissolution step is much simpler than for other methods of analysis, because the final measurement is the determination of the radionuclides formed by the irradiation. As the dissolution step is done after the irradiation is carried out, no contamination during the dissolution step can influence the final results. In addition, as the dissolution of the sample is done together with that of carriers, the danger of losing trace elements by adsorption is considerably lower. On the other hand, owing to the radioactivity of the irradiated sample, the dissolution, if performed many times, should be done behind lead shields. In principle, every chemical separation that is used in any other analytical method can be used in RNAA. But since the separation very rarely involves a single element, an appropriate group of elements which do not interfere with each other is different for various determination methods. This is the reason that it was decided that it was worth collecting together in this article the main methods of chemical separation into groups that are used in RNAA. In some cases, even the separation into groups is not needed, and it is sufficient to remove the major interferences. Egger and Krivan in their determination of trace elements in aluminum, removed only the interference of $^{24}$Na (by sorption on a hydrated antimony pentoxide, HAP, column) and were then able to measure 38 trace elements, all in concentrations of less than 1 ppb. For most other analytical methods the bulk of Al might need to be removed.

An additional aspect which is different for RNAA with respect to all other determination methods, is that in RNAA the final determination can be performed while the trace elements are adsorbed onto a separation column, whereas all other methods require the elution of the trace elements from the column.

2 SEPARATION IN MATERIAL SCIENCES

Park et al. studied the concentration of 13 trace elements in high-purity molybdenum by separating them into three groups, separated from the major interferences which are Mo and W. A cation exchange column (Dowex™ 50) in dilute HCl medium is used to remove Mo and W, which are only weakly adsorbed on this column, while many of the impurity elements are strongly absorbed. Na and K are eluted by using additional dilute...
HCl. Nine trace elements were eluted with 6-M HCl. Together with Mo and W, 238\textsuperscript{U} and 232\textsuperscript{Th}, which are the IRNs for U and Th, due to $\beta^-$ decay following the $(n,\gamma)$ reaction, were also eluted, respectively, Equation (1)

\[
238\textsuperscript{U}(n, \gamma) 239\textsuperscript{U} \xrightarrow{\beta^-} 239\textsuperscript{Np};
\]

\[
232\textsuperscript{Th}(n, \gamma) 233\textsuperscript{Th} \xrightarrow{\beta^-} 233\textsuperscript{Pa}.
\]

Np and Pa were separated from Mo and W using anion exchange (Dowex™-1) in strong nitric acid media. Pa and Np are strongly absorbed on the anion exchange resin, while molybdenum and tungsten are not. Figure 1 gives a schematic representation of the process of separation of Park et al.\textsuperscript{2}\textsuperscript{)} Before counting, each eluate was concentrated by partial evaporation.

Theimer and Krivan\textsuperscript{3}\textsuperscript{)} developed a group separation for the determination of 20 elements in high-purity molybdenum (Figure 2). They developed two modifications. The first one involves removal of Mo and its daughter Tc and the main contamination of W, by absorption on anion exchange resin (Dowex™-1X8). Five other elements are also absorbed on the column, but 20 elements are eluted and can be determined simultaneously in the eluate. The second modification allows determination of only 11 elements, although separation is effected into two groups. The advantage of this special modification is the separation of 233\textsuperscript{Pa} (the IRN of Th) with only Sc, enabling determination of small amounts of Th. Both modifications are based on elution with various concentrations of HF, similar to all the procedures developed by Krivan et al. for determination of trace elements in metals. The flow chart for the two radiochemical separation procedures is given in Figure 2. The two methods are based on Mo, Tc, and W being absorbed on an anion exchange column in HF media, while the trace elements are eluted with HF. For selective separation of Pa (together with Sc only), lower concentrations of HF are used. The elements given in parentheses are eluted but not completely, so that they are found both on the column and in the eluate. The elements determined via medium-lived IRNs and which had

to be in eluate 1 according to their distribution ratios, as for example Cu, Ga, K, Mn and Na, do not appear in procedure B, because about 1% of the technetium is eluted with this fraction, masking the activity of these IRNs. However, if (NH₄)₂S₂O₈ is added to the sample solution prior to its evaporation, in order to oxidize all technetium species to the heptavalent state, less than 0.01% of the technetium is found in fraction 1, and the other elements can also be determined in this fraction.

A similar technique was developed by Krivan’s group to determine the content of 19 elements in high-purity tungsten. However, a modification was done in order to measure the concentrations of Ta and Sb, which in the previous processes were adsorbed on the anion exchange resins together with Mo, Tc and W, and could not be determined. Ta and Sb are extracted with organic solvent (dichloroethane, DCE) after forming complexes with diantipyrilmethane (DAM), prior to the introduction of the solution of the dissolved irradiated tungsten onto the anion exchange column. In order to measure the P content via ³²P, a β⁻-only emitter, ³²P is substoichiometrically extracted as molybdophosphate with tetraphenylarsonium chloride in dichloromethane. The flow chart for this separation is given in Figure 3.

Figure 4 Two procedures for RNAA of trace elements in niobium (a) for medium-lived IRNs; (b) for long-lived IRNs. HDEHP, di(2-ethylhexyl)-orthophosphoric acid. (Based on figures from Caletka et al. with permission.)
Caletka et al.\textsuperscript{(6)} developed a RNAA procedure for determination of 26 elements in niobium by irradiation and processing of two samples, one for measurement of medium-lived IRNs (the radionuclide used for the determination of an element in NAA), by irradiation for 12 h. The second sample was irradiated for 5 days in order to determine the long-lived IRNs. In the determination of medium-lived IRNs, they wanted to measure \(^{56}\text{Mn}\) (\(t_{1/2} = 2.58\) h) and \(^{65}\text{Ni}\) (\(t_{1/2} = 2.52\) h) as well. This is possible because the main activity produced from the matrix (\(^{94m}\text{Nb}\)) is short lived (\(t_{1/2} = 6.24\) min) and one hour of cooling leaves a sample that is not too radioactive to handle. For matrices where the main activity is longer lived, IRNs with half-lives of a couple of hours can be determined only by pre-irradiation separation of the matrix, or treatment in special hot laboratories, where very high radioactivity can be handled. Different schemes of separation were devised for the medium- and long-lived IRNs, however, they have many common features. Both use solvent extractions followed by separation on columns. The same two solvent extractions were used in the two

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{Procedure_diagram}

\end{figure}
procedures, and the only difference is in the columns and acids used for separation of the last aqueous phase into three groups. The first extraction step is for cations which form chelates with dithizone and are extracted with chloroform. This fraction includes Cu, Au, Pd and Pt in the medium-lived IRNs, and Ag, Se in the long-lived IRN samples. The second extraction of metals is for those which form complexes with DAM. The organic solvent is DCE. This extraction is used to remove tantalum and niobium, and the organic phase containing them is discarded. The elements remaining in the aqueous phase are separated into three groups using two columns in series. One group is adsorbed on each column, and the third group contains the elements which were eluted from the two columns. For the long-lived samples, the first column is the reversed phase di-(2-ethylhexyl) orthophosphoric acid on a solid support which were eluted from the two columns. For the long-lived samples, the first column is the reversed phase di-(2-ethylhexyl) orthophosphoric acid on a solid support and then a column of anion exchange resin-Dowex™-1. For the medium-lived IRNs, the anion exchange-Dowex™-1 is the first column, followed by a HAP column. In high-concentration HCl solution, HAP retains only the Na ions; however, under the conditions used here, K also remained on the HAP column. The flow chart of the separation is given in Figure 4.

A thorough determination of the trace elements in ultrapure metal was performed for aluminum.(7) Previously, we mentioned that 38 elements were determined in levels of parts per billion, by selective removal of $^{24}\text{Na}$ with a HAP column. Later, the same group extended this study, and in order to improve the limits of detection, an additional separation into 10 groups was done.(7) Forty-three elements have limits of detection below 10 ppb, and for U and Th the limits of detection are 50 ppt ($5 \times 10^{-11}$). The separation scheme is given in Figure 5. First, Na$^+$ is retained on HAP. With 12-M HCl elution, this is the only cation to be retained. The eluate from the HAP column is loaded onto an anion exchange-Dowex™-1 column after the fourth elution. The original eluate from the HAP column is masked by addition of boric acid and the solution is introduced into another Dowex™-1X8 anion-exchanger column. The masking of anions by boric acid leads to retention of Pa (IRNs of Th and U) on the column. Further elements are separated on a cation exchanger. The solution is evaporated to dryness, dissolved in 0.1-M HCl and introduced into a cation exchanger Dowex™ 50X8 and washed with 0.1-M HCl. The eluate is one group of five elements, while the 27 elements remaining on the column are separated into three groups by two elutions.

The flow chart for the separation (Figure 5) shows the separation of 52 elements as studied by radiotracers. Not all of them were found in the ultrapure Al. Only those not in brackets were actually found in the irradiated Al.

3 GEOLOGICAL AND ENVIRONMENTAL SAMPLES

Many studies have been done on the determination of precious metals in geological samples. Nadkarni and Morrison$^{15,9}$ digested the irradiated sample...
(200–500 mg) by peroxide fusion, and separated the noble metals on a Srafion NMRR selective chelating ion-exchange resin. However, yields are not well reproducible and reirradiation of each sample is necessary to determine them. Only Pd, Pt, Ir and Au can be determined by this process. The use of the ion exchanger Srafion NMRR was questioned by Stockman, who could not repeat the results of Nadkarni and Morrison and attributed this to changes in the manufacture of the resin. There are also some previous data which give contrasting results for the specificity of this resin for d8 ions.

Chai et al. developed two different methods for radiochemical separation of the noble metals. They found that Nadkarni and Morrison were right and the Srafion NMRR resin can be used to retain Os and Ir. Ten milliliters of 0.05-M HCl eluted 100% of Sc, Cs, and Fe, whereas only 10% of Os was eluted. Nadkarni and Morrison reported that thiourea can be used to elute the noble metals, whereas Stockman argued that thiourea elutes only gold, while Ir remains on the resin. Chai et al. found that Ir and Re can be eluted with NH3, whereas only one-quarter of Os was eluted and no Au or Pt. Chai et al. found that all platinum group elements (PGE), including Au, are retained by various productions of this resin. Chai et al. suggested a scheme for radiochemical separation of noble metals, which is given in Figure 6. They found that their digestion process forms mainly Ir(III), which is not absorbed onto the chelate resin. However, oxidation of the chelated Ir with hot H2O2 transforms all Ir to the +4 oxidation state, which is absorbed on another column with the same resin.

An alternative process for the separation of the noble metals, suggested by Chai et al., is based on extraction of noble metals with long-chain primary amines (19–23 carbon atoms) in DCE. All the noble metals are extracted in high yields into the organic phase. The base metals were only negligibly extracted.

Another group besides the noble metals, which is determined many times by RNAA, is the rare earth elements (REE) group. Zilliacus et al. described two procedures for the separation of the REE group from irradiated geological samples. A simple and faster method was developed for samples with concentrations above 0.5 ppm, while a method with more separation steps was developed for samples with lower concentrations. A more time-consuming process is required to obtain a clean REE fraction. The two processes are described in Figure 7. Both methods are based on fusion with

![Figure 7 Separation scheme for the analysis of REE in geological samples (Reproduced from Zilliacus et al. with permission.)](image-url)
Na$_2$O$_2$ and cycles of precipitation as hydroxides and as fluorides. In the simple method there is one more step for removal of Sc and other metals by extraction with tributylphosphate (TBP). For the lower concentration samples, SiO$_2$ is removed by precipitation with gelatin in acidic solution, the main interferences are adsorbed on an anion exchange column in a HCl medium, while the REE are eluted. Sc is removed by extraction with ether from SCN$^-$/NUL$_2$ solution. Purification of the REE fraction is done by a cycle of precipitation of hydroxides and fluorides. A similar process was also developed by Laul et al.$^{16}$ They did not use the Sc removal step by extraction; however, in the final step, they performed three cycles of hydroxides–fluoride precipitation.

A similar method was developed by Wandless and Morgan.$^{17}$ The method is based on the precipitation of the REE hydroxides both at high pH and at pH 9 in ammoniacal solution. SiO$_2$ is removed by precipitation with gelatin in acidic solution. Fe is removed by an anion exchanger in the Cl$^-$ form from 8-M HCl solution. Zr, Sc and Hf are removed by an anion exchanger in the SCN$^-$/NUL$_2$ from 0.8-M SCN$^-$/NULC$_0.5$-M Cl$^-$ solution. The only remaining interference is Cr$^{3+}$, which is removed by precipitation of the REE with excess 8-M NaOH. The complete scheme is given in Figure 8.

Parthasarathy et al.$^{18}$ separated the REE into two groups rather than into one group, as in all other processes. They separated a group of light REE and a group of heavy REE. The process is different from all those previously described, and the flow chart is given in Figure 9.

Morrison et al.$^{19}$ described a procedure for chemical group separations, which, with the use of a Compton suppression Ge(Li) detector, can determine 45 elements in geological samples. The flow chart for this process is given in Figure 10. The first group is the one including volatile elements and volatile fluorides. Elements adsorbed to HAP in 8-M HCl formed the second group. Those adsorbed to anion exchange resin in 8-M HCl formed the third and fourth groups. The separation between these two groups is done by elution with 0.5-M HCl. The elements not adsorbed on the anion exchange in the 8-M HCl are separated into two groups by extraction with TBP. Laul et al.$^{20}$ developed a RNAA method for trace elements in terrestrial rocks and stony meteorites. They stated that their main emphasis was to minimize chemical procedure and maximize the γ-ray spectrometry aspect. However, their separation is longer than that of Morrison et al.$^{19}$ and they measure only 16 elements. The flow chart of their separation is given in Figure 11. The scheme involves four different separation techniques: distillation, solvent extraction, ion-exchange columns, and precipitation.

Smets et al.$^{21}$ developed a group separation for RNAA determination of 24 elements in a wide variety of silicate rocks and minerals. The samples were decomposed in a HF–HNO$_3$ mixture in a PTFE (polytetrafluoroethylene) lined bomb, and were separated into soluble and insoluble fluorides. The soluble fluorides were separated into three groups by sequential elution (0.1-M HF, 3-M HCl + acetone, 12-M HCl) from a cation exchange column. The insoluble fluorides (Ca, Sr, Ba, REE and part of Rb and Cs) were dissolved and purified from iron and scandium activities by extraction with TBP. The separation scheme is given in Figure 12. The elements written in large type were determined, whereas those elements in small

Pietra et al. developed 22 different RNAA procedures for environmental and biological samples. Many of these procedures are for several elements or for single elements; however, some are for group separations. The most extensive procedure (50 elements) was used only for biological samples. The next most extensive (39 elements) procedure was used for geological samples, and the separation scheme is depicted in Figure 13. The samples were dissolved in acid mixtures in a Teflon bomb, and, after drying, dissolved in 0.1-M HNO₃ which was also used as the only eluant. The trace elements were separated into five groups by the use of five different columns: acidic aluminum oxide (AAO), tin dioxide (TDO), copper sulfide (CuS), cadmium oxide (CdO) and HAP. The separation time for this procedure is about 2 h. All the IRNs were counted in the columns without elution. In another scheme where the geological material was dissolved in 6-M HF, the HAP column was used first, followed by the cation exchange column, and later an anion exchange column can be used to separate the mixture into four groups in which 35 elements can be determined. As in the previous scheme, in order to simplify the procedure and to make it easier for automation, only one eluant (6-M HF) is used.

Vasconcellos and Lima developed a procedure that is between several elements and a group separation. It is based on the use of three columns: HAP, anionic resin column and a reverse phase chromatography column with TBP on a Kieselguhr support. Several elements appeared in more than one fraction, but all the REE appear in one group and can be measured. The same is true for Na, Ta, Zn, Fe, Co, Cu, Ga, K, Ba, and Cr. The flow chart for the separation is given in Figure 14.
Figure 15 Pietra et al. scheme for radiochemical separation for the determination of 50 elements in biological samples. (Reproduced from Pietra et al. with permission.)
4 BIOLOGICAL SAMPLES

Many group separations were developed for biological materials. Some of them divide the sample into a few groups measured on a Ge(Li) or HPGe detector, while others perform very elaborate separations into many groups to enable activity measurements on very small amounts using a well-type NaI(Tl) detector. Figure 15 shows the flow chart of the Pietra et al. procedure for the determination of 50 elements. The procedure starts with distillation of the elements (Cl, Br, I, Os) and the chlorides–bromides (Sb, Sn, Hg, Au, As, Se, Ge, Re, Ru). The chlorides–bromides are separated into six groups (not more than two elements in the same group) by the use of two columns (first an anion exchanger and then TDO) with successive elutions. An arrow from the column means elution. Elements with arrows to the column are retained on the column. Elements in brackets are present in more than one group. The nonvolatile elements/chlorides/bromides are separated using successive elutions with six columns: anion exchanger, CuS, TDO, AAO, and cation exchanger. The procedure of Pietra et al. for the determination of 39 elements using five columns with a single eluant, which is described for geological material, was also used for biological material (Figure 13).

Although 50 elements can be separated and determined, most studies do not need so much information, and most studies measured 10–20 elements by more simple methods. Pietra et al. have several schemes for this purpose. van Renterghem and Cornelis determined 10 elements in human serum. Their procedure divides 13 elements (Na, K, and Br were not determined in the serum) into three groups by using an anion exchange column in the Br⁻ form with two elutions. The scheme is shown in Figure 16.

Sixteen trace elements were determined by the same group using three columns and one eluant as can be seen in Figure 17.

Schuhmacher et al. developed an almost complete scheme, in order to enable the activities to be measured with a well-type NaI(Tl) detector, to measure the contents of 25 trace elements in small biological samples (1–15 mg). The scheme is based on 14 consecutive columns divided into three Groups (3,7,4). For all columns in one group, the same eluant was used. Between the second and third group the eluate is automatically titrated to pH 2. The scheme is shown in Figure 18.

Figure 19 gives the scheme of Yeh et al. for group separation, measuring 21 elements, not including Na and Br, which can also be measured. This scheme includes distillation of Br as an element, a HAP column, As and Se distillation as bromides, and an AAO column. A more extensive review on RNAA can be found in Alfassi.

Small amounts of radionuclides of suitable half-life can be used to observe the kinetics of mass transport and isotopic exchange in the equilibrium distribution of a (micro-)component between coexistent phases.

Quantitative assay of radioactivity is sensitive, precise and accurate and usually performed instrumentally. Though handling of radionuclides is restricted to authorized laboratories only, the combination of its potential and simplicity makes the radiotracer method an indispensable part of modern analytical chemistry.

1 INTRODUCTION

Small changes in isotopic composition by addition of minute quantities of either stable isotopes or radionuclides offers the possibility of labeling ions and molecules without significant shifts in their thermodynamic properties. This “tracer” principle enables the observation of kinetics, including isotopic exchange and equilibrium distributions.

The measurement of stable tracers is performed by mass spectrometry, usually on small aliquots of solution. As a rule, assay of radiotracers may be achieved by direct β or γ counting of relatively large subsamples. In case of α-active radiotracers, sample pretreatment is mandatory to obtain a thin-layered counting aliquot.

Radiotracers are applied in authorized laboratories only. Owing to the sensitivity of detection, the amount of activity, expressed in disintegrations per second per Becquerel (Bq) can be at quite a modest rate, usually below 10^5 Bq. Such quantities can be handled with simple precautions in the many low-level tracer laboratories in hospitals, industry and university laboratories.

The most frequent application of the method is in medical diagnosis, followed by metabolic studies, environmental transport and availability experiments, including pilot plant simulations. The optimization of benchtop analytical procedures constitutes another established range of uses. This text concentrates on the principles of the radiotracer method and its nonmedical applications. A few illustrative cases have been taken from environmental studies, material science and analytical procedure development.

2 PRINCIPLE AND FORMULATION

2.1 General

The basic idea of the radiotracer method is the supposed identical behavior of stable and radioactive nuclides. Thus the presence of a tiny amount of an isotopic radionuclide, negligible in weight but well able to be detected by its radiation, enables observation of the “labeled” element. The chemical species of the radiotracer should be equal to that of the bulk mass in question. Thus both ions and (labeled organic) molecules are used. The small influence of the mass difference can be neglected in the large majority of applications. It becomes significant for light elements only, from about oxygen to elements of lower atomic mass, and in some artificial arrangements for isotope separation.

The signal obtained from a radiotracer depends on the concentration and the specific activity of the compound or phase which is being measured. In the case of a closed system, a radiotracer experiment gives information on the rate of the net mass-transport which affects the concentration, and on the rate of isotopic exchange which
influences the specific activity of the compound of interest. In open systems this distinction is not generally made but the variation of the signal is considered to be proportional to the changes in concentration.

2.2 Radiotracer Experiments in Closed Systems

The aim of radiotracer experiments in closed systems is to observe the interaction between two or more phases and compounds and, eventually, their equilibrium situation. Usually an amount of radioactivity is added as a component of one phase or compound and its quantity measured as a function of time. If the reaction between two compounds in one phase is examined, separation has to be performed prior to the measurement. Often an aliquot is taken for counting.

The result is a number of counts, \( A \), related to the specific activity, \( a \) (disintegrations s\(^{-1}\) g\(^{-1}\) or disintegrations s\(^{-1}\) mol\(^{-1}\)) and the concentration, \( c \) (g L\(^{-1}\) or M) by Equation (1)

\[
A = \gamma ac
\] (1)

The constant of proportionality, \( \gamma \) (in counts disintegration\(^{-1}\) s L or counts disintegrations\(^{-1}\) s mol), accounts for the volume of the aliquot and the counting conditions. At the beginning of the experiment Equation (2) follows

\[
A_0 = \gamma a_0 c_0
\] (2)

and thus, Equation (3)

\[
\frac{A}{A_0} = \frac{a}{a_0} \frac{c}{c_0}
\] (3)

If we now write Equation (4)

\[
f_A = \frac{A}{A_0}, \quad f_a = \frac{a}{a_0} \quad \text{and} \quad f_c = \frac{c}{c_0}
\] (4)

it follows that Equation (5)

\[
f_A = f_a f_c
\] (5)

and thus, with \( df/dt = f' \), Equation (6)

\[
f'_A = f'_a f'_c + f'_a f'_c
\] (6)

Equation (6), the activity balance, together with the mass balance, forms the basis of all radiotracer experiments in a closed system. In kinetic studies the third obvious equation is the rate balance: at equilibrium the net rate of two opposing reactions must be zero.

Without net mass transport \( f_c = 1 \) and \( f'_c = 0 \) and thus \( f'_A = f'_a \) and \( f_A = f_a \). In this case, a gradual isotopic exchange can be observed. If on the other hand there is no isotopic exchange, the reverse holds and \( f_A = f_c \), enabling the measurement of net mass transport.

When both \( a \) and \( c \) change during the experiment, extra information is needed to solve Equation (6). This may take the form of a separate determination of \( f_c \) or a logical prediction of \( f_a \). The various possibilities are summarized in Figure 1.

A clear distinction must be made between the amount of radiotracer which is present in the system and that which is available: in leaching experiments on radioactivated solids the available amount increases nonlinearly with time.

In general, the moment of introduction of the radioactivity does not coincide with the beginning of the

Figure 1 Survey of radiotracer experiments in a closed system.
interaction. By varying that moment, a (decreasing) ratio between net mass transfer and isotopic exchange may be observed.

Applications of radiotracer experiments to closed systems refer to interactions between compounds in one phase or different, adjacent, phases. As isotopic exchange or net mass transfer may be requested, this makes four possible combinations.

2.2.1 Isotopic Exchange

Generally, the reaction is of the type \( AB + A^*C \leftrightarrow A^*B + AC \). The asterisk indicates the radiotracer. By definition, the time of its introduction is taken as zero. By plotting the logarithm of the exchanged fraction against time, the rate constant can be obtained.\(^{(1–3)}\) A similar formalism is applicable to isotopic exchange between two adjacent phases.

2.2.2 Net Mass Transport and Final Spatial Distribution

The case of net mass transport at a constant specific activity is by far the most frequent among radiotracer applications. A complication arises when the total available amount of radioactivity changes with time, as in the leaching of radioactivated or labeled solids. The activity of the leachant is measured as a function of time. It is obvious that the specific activity will remain constant only when the fresh eluent does not contain this element of interest. The mass balance may be written as Equation (7)

\[
\frac{dc}{dt} = GF(t)
\]  

where \( V \) is the volume of eluent (mL), \( c \) is the concentration in the eluent (g mL\(^{-1}\)), \( t \) is the time (h), \( G \) is the amount of solid (g) and \( F(t) \) is the specific mass transfer function (g g\(^{-1}\) h\(^{-1}\)). Measurements of \( c \) as a function of \( t \) yields \( F(t) \).

Table 1 gives the empirical expression for \( F(t) \) and those for \( f_A \), the number of counts as a function of time for a leachant without or with some initial concentration of the analyte.

2.3 Radiotracer Experiments in Open Systems

Radiotracers are used in open environmental systems to measure flow rate and/or time of residence as well as their distributions. This is invariably done by a one-time (\( \delta \)-function) injection. Either the radioactivity is added to the system or induced by activation in small aliquots taken from the system. Unlike experiments in a closed system, \( f_c \) only is considered. Thus \( f_A = 1 \) and \( f_A = f_c \), implying that the radiotracer remains in its original phase.

In principle, there are no special rules involved in the use of a radiotracer as the tagging agent. Thus the formalism developed by Danckwerts\(^{(4)}\) and expanded in many textbooks, like that of Levenspiel,\(^{(5)}\) may be used. The distribution of the radiotracer over the effluent, \( f(t) \), is determined. From this the first and the second moment, average residence time and its variance are calculated. These measurements are mandatory in column leaching studies as the flow pattern influences the activity elution curve.

2.4 Limitations of Radiotracer Methods

Applications of radiotracers are restricted by fundamental as well as practical reasons. The limited choice of radiotracers and their half-lives and the isotope effects in reaction rates and equilibrium concentrations can be regarded as fundamental restrictions. The requirements for the operation of a radiochemical laboratory and the mandatory safety precautions in field experiments are of a practical nature.

The finite number of useful radionuclides and the limitations in their availability are reflected by any commercial catalogue. The most important consequence is the predominance of \( \beta \)-counting, usually by liquid scintillation, in physiological tracer experiments.

The influence of the mass difference between the natural isotopic mixture and the radiotracer can be expressed in terms of empirically determined correction factors for equilibria and reaction rates.\(^{(6,7)}\) In elements with atomic masses greater than oxygen, the effect is usually lower than 5%.
2.5 Practical Applications of Radiotracers

The numerous applications of radiotracers can be systematized by division into three broad categories:

- optimization and performance of laboratory determinations by chemical separation
- measurement of spatial distributions
- observation of phase equilibria and related kinetics.

Some major trends are given below.

2.5.1 Application of Radiotracers in Laboratory Determinations by Chemical Separation

Optimization and, eventually, actual performance of trace determinations in the analytical laboratory may be done efficiently by means of radiotracers. Inorganic applications usually rely on $\gamma$-emitting radionuclides, while organic (i.e. biological and medical) experiments are mostly based on $\beta$-emitters. A second distinction is that between off- and on-line measurements. Obviously, the latter are preferred whenever they are feasible.

An example of an inorganic application is met in the determination of Hg$^{II}$ in water by reduction with SnCl$_2$ and aeration; the escaping mercury vapor is trapped on active carbon.$^{8}$ Figure 2(a–c) illustrate to this procedure.

Radionuclides used in the separation and determination of organic trace compounds by high-performance liquid chromatography and off- or on-line counting are listed in Table 2; Figure 3 shows the flow-sheet of the apparatus.$^{9,10}$

The choice between off- and on-line counting depends on the scope of the experiment and the specific activity of the radiotracer. The advantages of off-line counting are the variable counting time, the stable and low count rate of the background and the absence of any influence of chemiluminescence. The accompanying disadvantages comprise the inevitable “breaking-up” of the originally continuous chromatogram, the risk of irreproducible fractions and the time-consuming laborious procedure. Off-line scintillation counting is convenient when a small number of well-separated peaks are expected and if the amount of radioactivity, governed by the specific activity, is low.

Flow-through detection with a water-miscible liquid scintillator implies its continuous addition, usually at flow rates between 0.1 and 1 mL min$^{-1}$ and subsequent mixing. The detector cell is $\sim$50µL in volume, thus appreciably larger than the usual $\sim$10µL cells of other detection methods. The advantages of flow-through counting are the automatic procedure and the high counting efficiency. The obvious disadvantage is band broadening in the cell.

Solvent segmentation based on postcolumn extraction/segmentation of the column eluate with a suitable liquid scintillation is the best option.$^{11}$

a Specific activities given are about the maximum values specified for commercially available radiolabeled compounds or elements. TBq mmol$^{-1}$ unless stated otherwise.

b The maximum range given is calculated for pure $\beta$-emitters in water from the formula: Range in g cm$^{-2}$ = $0.11[(1 + 22.4 E_b^{1/2}) - 1]$ with $E_b$ in MeV.

Figure 3 Apparatus for flow-through liquid scintillation counting. 1 = injector, 2 = fraction collector.

3 MEASUREMENT OF SPATIAL DISTRIBUTIONS

3.1 Survey

In assessing spatial distribution, radiotracers are most often used to measure net mass transfer of a previously spiked component within a known matrix. Thus radioanalysis is just one of the options. Conversely, the measurement of isotopic exchange is open to isotopic methods only. Here radioanalysis has to compete with mass spectrometry in measuring coefficients of self-diffusion.

The oldest application in spatial distributions is the study of self-diffusion in metals. Relevant uses are met in the profiling of doping agents in semiconductors, tomography and the determination of diffusion coefficients in wetted granular solids and in liquids. In industrial pilot plants and factories, radiotracers are used to measure linear velocity and dispersion as mentioned in section 2.3.

3.2 Profiling in Solids

Flat solid surfaces of spiked samples are probed for their trace concentration profiles by abrasion or controlled
dissolution, followed by measurements on the material removed or the remaining aliquot. In general the first approach gives better precision but the actual advantage over measurement on the remaining aliquot depends strongly on the concentration profile.

The thickness of the layer removed in one step usually varies between 0.5 and 10 µm with a lower limit of ~0.1 µm. The radiotracer method thus fills the gap between macroscopic removal of surface layers and the physical methods for the submicron range.

A severe limitation is imposed by the required properties of the radiotracer and the mandatory combination of a radiochemical and solid-state laboratory which is found only in some university institutes and a few industrial laboratories. The use of special polishing apparatus with copper discs is also implied to obtain a precision of less than 1 µm.\(^{(11)}\) The amount removed is determined by microbalance weighing at a precision of \(\lesssim 10 \mu g\).

Counting of the remaining aliquot is restricted to \(\beta\)-emitting radionuclides and is performed with a solid anthracene detector. Collection of the abraded material on the copper discs and the surface of the remaining aliquot is feasible within 1%. In the case of silicon HF dissolution is necessary which precludes the use of a liquid scintillator for \(\beta\)-emitters and restricts detection to Cerenkov counting and individual quenching correction.

### 3.3 Radiography and Tomography

There is no possibility or need to discuss the whole field of present day radiotracer-based radiography. Its use in biology and medicine as thin layer radiochromatography is obvious. As a relatively new feature, the use of storage phosphor screens can be mentioned, as this has increased sensitivity and widened the applicability of double labeling procedures.\(^{(12)}\)

From the beginning of the 1980s, computer-aided tomography of three-dimensional objects became a new branch of radionuclide application.\(^{(13)}\) As with radiography, this text does not endeavor to treat this new specialization in detail; only principles are signaled.

Tomography is either based on the variation of the object’s own \(\gamma\)-count rate with the position towards the detector or on the change in attenuation of transmitted photons or neutrons. The first approach may be based on previous neutron activation\(^{(14)}\) or an added tracer; the last option belongs to the medical imaging techniques which will not be considered here. Industrial and nuclear waste tomography use the same principle.\(^{(15)}\) The full width at half maximum of the scanning of a \(^{198}\text{Au}\)-source was ~7 mm in the early experiments. Much better spatial resolution is obtainable in examining used fuel elements through a \(\lesssim 1 \text{ mm}\) slit of \(\sim 1 \text{ m}\) length, as performed at ECN, Petten.

Using a \(^{241}\text{Am}\) (59.5 keV) and a \(^{137}\text{Cs}\) (661 keV) source in conjunction with collimators of 1–5 mm and distances of 50–150 mm resulted in full width at half maximum of 5–40 mm.\(^{(16)}\) Comparable values (9–18 mm) were obtained in transmission and \(^{131}\text{I}\)-based emission experiments with phantoms.\(^{(17)}\) Off-line measurements on a neutron-activated bone sample by way of \(^{24}\text{Na}\), \(T^{1/2} = 15 \text{ h}\), gave a spatial resolution of 1–2 mm.\(^{(18)}\)

On-line measurements in the \(1.8 \times 10^{12} \text{ cm}^{-2} \text{ s}^{-1}\) neutron beam at the Grenoble HFR gave ~7 mm full width at half maximum for \(\text{CdCl}_2\) test pellets of that size.\(^{(19)}\)

Apart from the routine measurements on used fuel elements, as performed at ECN, no systematic application of radionuclide-based tomography is reported: simulated fuel\(^{(19)}\) and a test loop experiments with \(^{24}\text{Na}\)\(^{(20)}\) are scarce examples. In sharp contrast, the use of radioactive sources in industrial trouble-shooting as “go devils” is an established practice.

### 3.4 Diffusion in Wetted Granular Solids

Probably the most practical consequence of differences in element speciation is the variation in environmental mobility. Obviously the water content and the apparent diffusion coefficient of an inert tracer, i.e. one which does not interact with the solid, have to be determined. These data will then serve as reference values.

The use of a miniaturized system for diffusion measurements was first demonstrated in the case of traces of \(^{239}\text{Pu}\). Then it was applied to self-diffusion under equilibrium conditions.\(^{(23)}\)

Two identical cylinders are pressed together in a syringe. One part contains the radionuclide; the diffusion into the other section is measured. If a “weightless” spike is used, operation is under equilibrium conditions. This procedure yields the coefficient of self-diffusion, which for trace constituents is equal to the effective diffusion coefficient. When a component is involved which is present in solution only the apparent diffusion coefficient(s) obtained reflect(s) the tortuosity and constructivity of the void fraction(s). Experimentally, these two effects combine into one “restriction factor”.

If a component is present in both the solid and the liquid phase and if the added radiotracer exchanges rapidly over the phase border, its diffusion will reflect the distribution ratio. When the element involved is present in more than one chemical form the result of the diffusion experiment will depend on the rate of isotopic exchange between the added spike and the (other) species. Only in the limiting cases of either very rapid exchange or no exchange at all, radiotracer diffusion will yield valuable information. Rapid exchange leads to the determination of the mass-averaged apparent diffusion coefficient. No exchange at
RADIOTRACER METHODS

all implies the determination of the apparent diffusion coefficient of the spiked chemical form. The simple diffusion Equation (8) applies to a radiotracer which is exclusively present in solution and in one chemical form only and for the case of semi-infinite media.

\[
\frac{\partial (ac)}{\partial t} = D \frac{\partial^2 (ac)}{\partial x^2},
\]

(8)

where \( a \) is the specific activity (Bq g\(^{-1}\)), \( c \) is the concentration (g L\(^{-1}\)), \( D \) is the coefficient of self-diffusion (m\(^2\) s\(^{-1}\)), \( x \) is the position (m) and \( t \) is time (s).

At chemical equilibrium, for a “weightless” spike, this expression reduces to Equation (9)

\[
\frac{\partial a}{\partial t} = D \frac{\partial^2 a}{\partial x^2},
\]

(9)

From a plot of ln\( a \) against \( x^2 \) and curve fitting to the solution of Equation (9) for a finite system\(^{22}\), the apparent diffusion coefficient together with information about the eventual coexistence of more than one flow-channel and their relative importance are obtained.

Under equilibrium conditions and with rapid isotopic exchange Equation (10) gives the experimentally apparent \( D \)-value

\[
D_e = \frac{D/r}{1 + (m_S/m_L)}
\]

(10)

where \( D \) refers to the “true” or unretarded diffusion coefficient in an aqueous solution, \( r \) to the mentioned restriction factor and \( m_S/m_L \) to the ratio of the exchangeable masses of the element involved in the solid and liquid phases. Whether the assumption of fast isotopic exchange is valid or not can be verified by varying the time lag between the application of the radiotracer to one compartment and the actual joining of the two sections. If this has no influence on the result, the condition is fulfilled.

As an inert radiotracer, tritiated water is used. Environmental investigations refer most often to anions as these feature the highest mobilities. Suitable radiotracers are \(^{74}\)AsO\(_3^\text{III}\), \(^{75}\)SeO\(_3^\text{IV}\), and \(^{75}\)SeO\(_2^\text{V}\), \(^{99}\)MoO\(_3^\text{IV}\) and \(^{124}\)SbO\(_3^\text{III}\). It can be concluded that a specific activity of \( \leq 10 \) mCi g\(^{-1}\) is sufficient for adding a “weightless” spike of \( \leq 20 \) µg g\(^{-1}\).

Figure 4 summarizes the procedure. About 3 g of the sample material is mixed with 0.9 mL of tracer solution and carefully homogenized. The diffusion tube consists of polythene with internal diameter 8 mm and length 70 mm. The interface of the two segments is gently marked with a tiny drop of \(^{170}\)Tm solution.

After a storage time of 5–15 days, the combined segments are taken out, frozen in liquid nitrogen and sliced into 0.5–1 mm coupes. These are dried, weighted and counted. Data are processed to find the most likely \( D \)-value. Figure 5 gives the result for the diffusion of tritiated water through a fly-ash. The estimated value of the apparent diffusion coefficient is expressed as \( pD_e \). The usual error is 0.1 unit.
3.5 Diffusion in Liquids

The precise and accurate determination of diffusion coefficients of trace constituents (either of ionic or of molecular nature) in dilute, mostly aqueous, solutions is one of the obvious uses of radiotracers in the field of spatial speciation.

The main advantage of radiotracer experiments here, as in wet granular solids, is the possibility of measuring at zero diffusion gradient. Two techniques have been put forward, based respectively on a glass frit diaphragm and an open capillary within a large tank.

Initially, a diaphragm cell of ~100 mL was used. Later, the capillary procedure came into use, offering the advantage of a small spiked volume of ≥10 µL per capillary. It implies stirring the outside solution and thus requires rigorous precautions against turbulent flow and mechanical dragging of the spiked liquid from the capillaries. In the final version just one capillary is used, mounted within the well of a bored-through plastic scintillator which monitors continuously the remaining radioactivity. The whole apparatus is mounted in a thermostated room. With a (small) correction for the radioactivity, the whole apparatus is mounted in a scintillator which monitors continuously the remaining radioactivity.

Reports on the use of the capillary procedure are found in Kepak et al. and Podhajecky et al., while a reexamination of the diaphragm procedure is given by Podhajecky et al.

4 OBSERVATIONS ON PHASE EQUILIBRIA AND RELATED KINETICS

4.1 Survey

Within a system in (apparent) equilibrium, elements often occur in different physical phases. The potential use of radiotracers in measuring these distributions, and the kinetics with which they are reached, is obvious. The early, often “classical”, applications are mentioned in most textbooks on radiochemistry. The number of literature reports on the subsequent use in all branches of science, technology and medicine is enormous. Virtually all applications refer to the measurement of net mass transport (cf. section 2.2).

Current literature abounds with (more or less) defined procedures for physical speciation, particulate matter and colloids in natural waters and availability measurements on trace metals in granular solid wastes. Eventual these investigations pertain to the occurrence and distribution of radionuclides from nuclear bomb tests and waste reprocessing. Quoted references give some examples only.

A methodical application is comparison of analytical techniques on water containing particulate matter. Equally, preconcentration and storage have been examined with the help of radiotracers. The contact time between water sample and container, whether polythene or glass, should not exceed more than a few minutes. In situ immobilization, eventually combined with preconcentration, is imperative. Scavenging with active carbon after adsorption of a suitable chelating agent is a possibility. Collection on Chelex-100 or on a combination of an anion and cation exchanger is well known; a survey is given by Florence.

Freezing, in combination with freeze-drying, is the best way of preserving the sample in its original state. Acidification to pH ~ 1–2 is justified only after thorough elimination of particulate matter, to avoid desorption. Using 203Hg, it was found that HgII desorbs completely at pH = 0.1 with a half-life of ~30 min.

The quest for well-defined and generally applicable speciation schemes has been successful in a few cases only. The separation of colloids from fresh water samples by the hollow fiber technique is an example; the standard leaching test on coal fly-ash is another, although a recent comparison revealed some systematic discrepancies between the various modes. Sequential leaching of soils by a series of increasingly aggressive solutions has been applied in a multitude of schemes, all of limited significance. Several articles giving examples have been published.

Applications of radiotracers to adsorption and desorption measurements and in isotopic exchange experiments were mentioned in section 2. Three practical applications are considered here:

- measurement of speciation controlled diffusion through soils
- kinetic association experiments with colloids in water
- evaporation kinetics of traces or organic pollutants from surface water

4.2 Speciation-controlled Diffusion

Figure 6 outlines the apparatus used. The “steady state” experiment imposes a linear gradient over the test sample but it takes a considerable time to reach it. Typical experiments with sand samples take ~10³ h. The radionuclide concentration in the unspiked reservoir is always much lower than that in the spiked compartment. This eliminates back diffusion.

The concentration in the unspiked cell is monitored until its rate of increase becomes constant. Relevant mathematics are given by Crank. The crucial feature is that d²c/ax² is zero and thus dc/ax is constant.
constant was determined for both I from a separate equilibration tank. enable the use of large aliquots of groundwater, taken section 4.1, except for its much larger dimensions. These two cylinders of material, one of them spiked, pressed with \(125I(\text{250 mL})\).

The majority of naturally occurring \(^{60}\text{Co}\) and added \(^{65}\text{Zn}\) is in the \(>10^4\) D fraction. An alternative to dialysis may be found in electrophoresis. Free liquid electrophoresis was applied to speciation studies of radium in natural waters using \(^{224}\text{Ra}\) as the radiotracer. Results indicate that in \(10^{-2}\) M chloride solutions the Ra\(^{II}\) cation is the main chemical species between pH = 2 and pH = 7.

4.3 Kinetics of Colloid Association
The use of spikes in radiotracers to determine recoveries in physical and chemical separations is obvious. Their most apparent application is met in the experiments on hollow fiber preconcentration, using an “Amicon” apparatus, of naturally occurring radionuclides. Cartridges with nominal molecular weight cut-off of \(10^5\), \(10^4\) and \(10^3\) are applied. Isolated fractions are analyzed by \(\gamma\)-spectrometry.

Kinetic association experiments are performed with the apparatus shown schematically in Figure 7. The sample is introduced into the test chamber and transported by a peristaltic pump to a mixing chamber and separator. The ultrafiltrate returns to the test chamber while the retained colloids go to the mixing chamber. The decrease in tracer radioactivity in the test solution reflects dilution, association with naturally occurring colloids and, eventually, sorption to the equipment.

It is found that equilibrium is usually reached in 1–2 h. The majority of naturally occurring \(^{60}\text{Co}\) and added \(^{65}\text{Zn}\) is in the \(>10^4\) D fraction.

Figure 7 Equipment for the measurement of trace element association with colloids. After Salbu.

4.4 Evaporation Kinetics of Traces of Organic Pollutants
Radiotracers are applied to environmentally important kinetics. In evaporation measurements, the overall mass transfer coefficient, \(K\), in mol min\(^{-1}\) cm\(^{-2}\) has to be obtained. To this end, evaporation experiments are conducted with labeled trace constituents from open vessels with a known gas–liquid surface area. The concentration of the (volatile) trace compound decreases exponentially with a characteristic constant \(KS/V_L\) for a given surface area \(S\) (cm\(^2\)) and liquid volume \(V_L\) (mL).

In a closed flask, the equilibrium concentration in the solution reflects the thermodynamic potential of the
trace constituent in the liquid phase. By measuring this equilibrium as a function of the initial concentration, eventual deviation from ideality can be detected.

“Carrier-free” \(^3\)H- or \(^14\)C-labeled compounds are used to spike stock solutions of the chemicals of interest. With commercially available specific activities of \(~1\ TBq \ m\text{ mol}^{-1}\), a liquid volume of \(~50\ mL\), an aliquot size of \(2\ mL\) and a counting time of \(100\ min\), the limit of determination at \(\sigma_{\text{rel}} \sim 1\%\) is \(10^{-2}\ ppb\). For \(^14\)C-labeled compounds of \(~2\ GBq \ 4\)C (m mol\(^{-1}\)) the lower limit is \(~5\ ppb\).

**REFERENCES**

Rutherford backscattering spectroscopy (RBS) is one of the most powerful techniques for measuring elemental depth profiles. It allows quantitative and nondestructive analysis with a reasonable depth resolution. In conventional RBS (combination of 1–4 MeV He ions with a silicon surface-barrier detector), the typical depth resolution is about 10 nm and the typical mass resolution is about 1 u for light elements (mass number \( M < 20 \)) and about 20 u for heavy elements (\( M \approx 200 \)). Sensitivity of 100 ppm can be easily obtained for heavy elements in light hosts although analysis of light elements in heavy hosts is difficult. In the present article, physical concepts which RBS relies on are briefly introduced. Some examples of analyses are demonstrated and several advanced techniques which have been developed to improve capabilities of the conventional RBS are discussed.

### 1 INTRODUCTION

The analysis of the surface and near-surface region of solids has become an important field of science and technology. RBS is one of the most powerful methods among a number of analyzing techniques. In RBS, high-energy ion beams, usually H or He ions with energies in the range 1–4 MeV, are used as probes. A sample is irradiated by the ion beam. Almost all ions penetrate deep inside the sample up to ca. 10 µm until they entirely lose their kinetic energy. During the penetration, some ions collide with the target atoms and are subject to elastic Coulomb scattering (Rutherford scattering) between the projectile and the target nuclei and may be backscattered from the sample. The energy of the ion backscattered from the target atom depends on the target atom mass. This allows compositional analysis of a surface region of several micrometers by measuring the energy spectrum of the backscattered ions. Figure 1 illustrates a schematic set-up of RBS and an example of an energy spectrum for a two-element thin film on a low-mass substrate. The ions scattered from each element form a separated peak. The number of target atoms in the film can be derived from the peak yields and the peak width gives the film thickness. Table 1 summarizes the features of standard RBS and can be used as a rough guide.

The method was first employed by nuclear physicists to analyze their targets in 1951.\(^1\) Extensive application to material science began in the late 1960s. The technique has been refined and now constitutes one of the most common methods for compositional analysis of the surface region. RBS has many outstanding features:

1. RBS is a nondestructive method of analysis.
2. It allows quantitative analysis of all elements simultaneously except for hydrogen.
3. RBS has a depth resolution typically of about 10 nm, which can be improved up to monolayer resolution in the surface region with special equipment.
4. The measurement time is typically as short as several minutes.
5. Sensitivity of RBS is about 100 ppm for heavy elements although it is not so good for light elements.

RBS relies on the following physical concepts:

1. The kinematic factor of the elastic scattering which describes the reduction of incident energy in a collision between the probe ion and the target atom.

SSB, silicon surface barrier.

The resulting energy of the scattered ion increases with target atom mass. This allows identification of the target atom by measuring the scattered ion energy.

2. The differential scattering cross-section which gives the probability of scattering. This allows basic quantitative analysis without a standard sample.

3. The stopping power which is defined by the energy loss of the ion per unit path length inside the target. The energy of the backscattered ion depends on the depth from which the ion was scattered because the path length is proportional to the depth. This allows the depth profiling of elements in the target.

4. The energy-loss straggling which is the fluctuation of the energy loss arising from the statistical feature of the energy-loss process. This determines the intrinsic depth resolution.

There are numerous reviews on RBS and for the state of the art reader can refer to relevant conference proceedings such as ion beam analysis (IBA), Conference on the Application of Accelerators in Research and Industry (CAARI), European Conference on Accelerator Applications in Research and Technology (ECAART) and Nuclear Microprobe Technology and Applications (NMTA). Most have been published in *Nuclear Instruments and Methods* in the Physics Research section B.

2 FUNDAMENTALS

2.1 Kinematics of Ion–Atom Collisions

When an ion is scattered from a target atom at an angle $\theta$, the ratio of the scattered-ion energy $E$ to the incident energy $E_0$ can be calculated using the laws of conservation of energy and momentum, Equation (1)

$$K = \frac{E}{E_0} = \frac{(M_1^2 - M_2^2 \sin^2 \theta)^{1/2} + M_1 \cos \theta}{M_1 + M_2}$$

(1)
where \( M_1 \) and \( M_2 \) are masses of the incident ion and the target atom, respectively. The binding energy of the target atom and its thermal vibration are neglected in the derivation of Equation (1). These effects are negligibly small in collisions between ions with megar electron volt energy and target atoms. It is clear that the energy ratio \( K \), called the kinematic factor, is determined by the mass ratio \( M_2/M_1 \) and the scattering angle \( \theta \). The basic idea of RBS relies on this equation. Figure 2 shows the kinematic factor as a function of the mass ratio \( M_2/M_1 \). The kinematic factor, and thus the energy of the scattered ion, increases monotonically with the mass ratio indicating that the target atom mass can be determined from the observed energy of the scattered ion.

The mass resolution is defined by Equation (2)

\[
\delta M_2 = \delta E E_0 \left( \frac{dK}{dM_2} \right)^{-1}
\]

where \( \delta E \) is the overall energy resolution of the RBS system. The dominant contribution to \( \delta E \) comes from the energy resolution of a SSB detector which is commonly used in RBS. Figure 3 displays the calculated mass resolution for 2-MeV H, He, and C, ions, where the typical energy resolutions of the SSB detector (i.e. \( \delta E = 10, 15, \) and 50 keV for H, He, and C, respectively) are used for \( \delta E \). The results at different scattering angles are also shown for 2-MeV He ions. A mass difference of 1 u can be resolved for light elements (\( M_2 < 40 \) u) with 2-MeV He ions. The resolution, however, becomes worse very rapidly with increasing \( M_2 \) and reaches \( \delta M_2 \) ca. 20 u at \( M_2 \) ca. 200 u.

For better mass resolution, heavy ions are usually employed. Although the energy resolution of the SSB detector is worse for heavy ions, the resulting mass resolution for C ions is better than for He ions and \( \delta M_2 = 1 \) u is achieved up to \( M_2 \) ca. 50 u with 2-MeV C ions. The resolution can be improved considerably using the time-of-flight (TOF) technique for energy analysis instead of the SSB detector in heavy ion RBS (HIRBS). The details of the heavy ion RBS will be discussed in section 4.1.

2.2 Rutherford Cross-section

The scattering cross-section \( \sigma \) is an effective area associated with the colliding particles. When projectile ions impinge on a thin target film of thickness \( t \), the scattering yield is given by Equation (3)

\[
Y_{\text{tot}} = \frac{N_0 \sigma Q}{\cos \alpha}
\]

where \( N \) is the volume density of the target atom, \( Q \) the number of incident ions, and \( \alpha \) is the incident angle (the definition of \( \alpha \) is shown in Figure 1). In RBS, the ions scattered at a particular scattering angle \( \theta \) are measured by a detector with a finite acceptance solid angle \( \Delta \Omega \). The number of these ions can be calculated (Equation 4) with an angular differential cross-section \( d\sigma/d\Omega \)

\[
Y(\theta) = N_0 \frac{d\sigma}{d\Omega} \frac{\Delta \Omega Q}{\cos \alpha}
\]

The differential cross-section for Coulomb scattering (Rutherford cross-section) is given by an analytical formula (Rutherford formula), Equation (5)

\[
\left( \frac{d\sigma}{d\Omega} \right)_R \left( \frac{Z_1 Z_2 e^2}{4E} \right)^2 \times \frac{4 \sqrt{(M_2^2 - M_1^2 \sin^2 \theta) + M_2 \cos \theta}}{M_2 \sin^4 \theta \sqrt{M_2^2 - M_1^2 \sin^2 \theta}}
\]

![Figure 2](attachment:image2.png) Figure 2 Kinematic factor \( K \) as a function of the ratio of the target mass to the ion mass \( M_2/M_1 \).

![Figure 3](attachment:image3.png) Figure 3 Mass resolution for 2-MeV H, He and C ion beams as a function of target mass \( M_2 \). Typical energy resolution of the SSB detector is used in the calculation.
where \( Z_1, Z_2 \) are atomic numbers of incident ion and target atom, respectively and \( E \) is the incident energy. This simple formula guarantees to extract quantitative data about abundances of elements from RBS spectra. The cross-section is proportional to \( Z_2^4 \), indicating high sensitivity for heavy elements in RBS. A useful number in evaluating the Rutherford cross-section is \( e^2 = 14.4 \text{ eV} \cdot \text{Å} \) (1 Å = \( 10^{-10} \text{ m} \)). For example, 1 MeV He\(^+\) ions of total dose 1 \( \mu \text{C} \) are incident on a Si film of \( t = 1000 \text{ Å} \) at \( \alpha = 0^\circ \). The differential cross-section is calculated to be \( \frac{\text{d} \sigma}{\text{d} \Omega}_{\text{R}} = 1.126 \times 10^{-8} \text{ Å}^2/\text{sr} \) at \( \theta = 150^\circ \). Using a typical acceptance angle of SSB detectors, \( \Delta \Omega = 5 \text{ msr} \) the yield is given by Equation (6)
\[
Y = 4.994 \times 10^{-7} \text{ Å}^{-3} \times 1000 \text{ Å} \times 1.126 \times 10^{-8} \text{ Å}^2/\text{sr}^{-1} \\
\times 5 \times 10^{-3} \text{sr} \times \frac{1 \times 10^{-6}}{1.602 \times 10^{-19}} \approx 17500
\]
The associated statistical error is \( 1/\sqrt{17500} = 0.8\% \). This means the thickness of the film can be determined with an accuracy less than 1\% in this case.

2.3 Non-Rutherford Cross-sections

The Rutherford cross-section can be used in situations where the incident ion energy is in the order of 1 MeV \( \text{u}^{-1} \). The cross-section deviates from the Rutherford formula in both high-energy and low-energy regions. On the low-energy side, the screening effect due to the bound electrons in the target atom reduces the cross-section from the Rutherford formula. The cross-section cannot be given by a simple analytical formula like Equation (5). The screened Coulomb potential is given by Equation (7)
\[
V(r) = \frac{Z_1 Z_2 e^2}{r} \phi \frac{r}{a}
\]
where \( \phi \) is the screening function and \( a \) is the screening length. There are several analytical formulas for the screening function given by a sum of exponential terms, Equation (8)
\[
\Phi(z) = \sum_{i} \alpha_i e^{-\beta_i z}
\]
where \( \{ \alpha_i \} = \{ 0.1, 0.55, 0.35 \} \) for Molière’s screening function \( ^{(6)} \) \( a = 0.8853 a_{\text{R}} (Z_1^{1/2} + Z_2^{1/2})^{-2/3} \) is commonly used and \( \{ \beta_i \} = \{ 6.0, 1.2, 0.3 \} \) for \( R \) atom, \( \{ \alpha_i \} = \{ 0.181 75, 0.509 86, 0.280 22, 0.028 171 \} \), \( \{ \beta_i \} = \{ 3.1998, 0.942 29, 0.402 90, 0.201 62 \} \) for Ziegler–Biersack–Littmark’s screening function \( a = 0.8853 a_{\text{R}} (Z_1^{23/25} + Z_2^{23/25})^{-1} \) is used.\(^{(7)}\)

Using the screening function, the differential cross-section can be calculated numerically. Algorithms for rapid computations are proposed by Mendenhall and Weller.\(^{(8)}\) A useful analytical formula for the screening correction valid for large scattering angles is given by L’Ecuyer et al.,\(^{(9)}\) Equation (9)
\[
\frac{\text{d} \sigma}{\text{d} \Omega} = 1 - 0.049 Z_1 Z_2^{4/3} \\
E_{\text{CM}}
\]
where \( E_{\text{CM}} \) is the center-of-mass kinetic energy in kiloelectron volts. Examples of the results calculated with Equation (9) together with the result of exact numerical calculation are shown in Figure 4. The deviation from the Rutherford cross-section is large for heavy elements and the correction formula for Equation (9) is reasonably good for both heavy and light elements. Although the deviation for 1-MeV He–Au scattering is about 4\% and the Rutherford formula may not be used in a precise measurement, Equation (9) can be safely used even in this situation. It must, however, be noted that Equation (9) does not contain the scattering angle \( \theta \) and is valid only for large \( \theta \). At smaller scattering angles, the screening effect becomes large.

On the high-energy side, the incident ion may approach to the target nuclei within the range of the nuclear force. This causes deviation from the Rutherford cross-section. The deviation is large for light elements because the Coulomb barrier of the nucleus is low for light elements. An empirical formula to estimate the threshold energy, above which the deviation from the Rutherford cross-section for \( 160^\circ < \theta < 180^\circ \) is larger than 4\%, is given by Leavitt and McIntyre,\(^{(10)}\) Equations (10–12)
\[
E_{\text{th}} = (0.12 \pm 0.01) Z_2 - (0.5 \pm 0.1) \text{ MeV for H} \quad (10) \\
E_{\text{th}} = (0.25 \pm 0.01) Z_2 + (0.4 \pm 0.2) \text{ MeV for He} \quad (11) \\
E_{\text{th}} = (0.330 \pm 0.005) Z_2 + (1.4 \pm 0.1) \text{ MeV for Li} \quad (12)
\]

![Figure 4](image-url) Screening correction for the scattering cross-section as a function of the incident ion energy. The results of the numerical calculation (solid lines) as well as those of the analytical formula (dashed lines) are shown for He–Si and He–Au scattering.
In contrast to the correction for screening effect, no practical methods exist for rapid accurate estimation of the nuclear force correction. The cross-section depends on both the ion energy and the scattering angle in a complicated manner (e.g. Figure 14). Nevertheless, high-energy ions are useful in some cases, especially in analysis of light elements. The standard RBS is less sensitive for light elements due to the small Rutherford cross-sections of light elements (the cross-section is proportional to the square of the target atomic number). The non-Rutherford cross-sections for light elements are frequently enhanced by one or two orders of magnitude while those for heavy elements may remain as a Rutherford cross-section. This improves the sensitivity for light elements. The details will be discussed in section 4.4.

2.4 Stopping Power

An energetic ion passing through a solid loses its energy primarily through excitation of electrons. The rate of the energy loss per unit path length, \( \frac{dE}{dx} \), is called stopping power and understanding the stopping power has been a subject of extensive studies. Using the first-order perturbation theory, the stopping power is given by\(^{(11)}\) Equation (13)

\[
\frac{dE}{dx} = \frac{4\pi Z_i^2 Z_f^2 \alpha^4}{mV^2} \ln \left( \frac{mV^2}{I} \right)
\]

(13)

where \( m \) is the electron mass, \( V \) the velocity of the ion, and \( I \) \((\approx 10 \times Z^2 \text{eV})\) is the mean excitation energy of the target electrons. This equation, called the Bethe–Bloch formula, is used as a guide in semi-empirical fitting of stopping power data to provide semi-empirical formulas. A number of tables are available to calculate stopping powers reasonably accurately.\(^{(7,12–14)}\) Figure 5 shows examples of the stopping powers of Si and Au for H and He ions calculated with the tabulated values given by Andersen and Ziegler.\(^{(12,13)}\) The stopping power has a broad maximum around 1 MeV for He ions and around 100 keV for H ions. The maximum energy and the maximum stopping power increases with both projectile and target atomic number. The stopping power for megaelectron-volt He ions is several times larger than that for megaelectron-volt H ions. This indicates that better depth resolution is available for He ions.

In order to estimate the stopping power of a compound, it is convenient to introduce stopping cross-section defined by Equation (14)

\[
\varepsilon = \frac{1}{N} \left( \frac{dE}{dx} \right)
\]

(14)

The stopping power of a compound \( A_m B_n \) can be calculated using Bragg’s rule, which is based on the simple assumption that the constituent elements act independently in the energy loss process, Equation (15)

\[
\left( \frac{dE}{dx} \right)_{A_m B_n} = N_{\text{mol}} \left[ me(\text{A}) + n\varepsilon(\text{B}) \right]
\]

(15)

where \( \varepsilon(\text{A}) \) and \( \varepsilon(\text{B}) \) are the stopping cross-sections of the constituents and \( N_{\text{mol}} \) is the molecular density. This neglects the effect of chemical bonding but gives reasonably accurate values for megaelectron-volt light ions.

The relationship between the energy of the scattered ion and the depth at which the ion is scattered can be calculated using the stopping power, the kinematic factor, and the geometry of the scattering. Neglecting the variation of the stopping power along the ion path, the energy of the ion scattered from a target atom at a depth \( t \) is given by Equation (16)

\[
E(t) = K E_0 - \left( \frac{dE}{dx} \right)_{\text{in}} \frac{t}{\cos \alpha} - \left( \frac{dE}{dx} \right)_{\text{out}} \frac{t}{\cos \beta}
\]

(16)

where the subscripts in and out refer to the inward path and outward path, respectively, and \( \alpha \) and \( \beta \) are the incident and exit angles, respectively. For a thin surface layer, the variation of the stopping power is small and the use of an average value is a good approximation. The variation in energy \( \delta E \) corresponds to a variation in depth \( \delta t \) through Equation (17)

\[
\delta E = -[S] \delta t
\]

(17)

where \([S]\) is commonly called the energy-loss factor and is given by Equation (18)

\[
[S] = K \left( \frac{dE}{dx} \right)_{\text{in}} \frac{1}{\cos \alpha} + \left( \frac{dE}{dx} \right)_{\text{out}} \frac{1}{\cos \beta}
\]

(18)
The depth resolution depends on the overall energy resolution, the stopping power, and the geometry. The energy resolution is normally composed of three contributions: the energy spread of the incident beam $\delta E_{\text{in}}$, the detector resolution $\delta E_d$, and the energy loss straggling $\delta E_s$ (the last of these, $\delta E_s$, will be discussed in detail in the next section). Assuming these contributions are independent, the overall resolution is given by Equation (19)

$$\delta E^2 = (\delta E_{\text{in}})^2 + (\delta E_d)^2 + (\delta E_s)^2$$

For example, in the case of 2-MeV He on Au at $\alpha = 0^\circ$ and $\beta = 30^\circ$ ($\theta = 150^\circ$), the energy-loss factor is calculated to be 135 eV Å$^{-1}$. Using a typical energy resolution in the standard RBS, $\delta E = 15$ keV and a depth resolution of 11 nm is obtained. The depth resolution can be improved up to ca. 2 nm simply by using a grazing-angle technique, usually with a grazing exit angle, for example $\beta$ ca. $85^\circ$. In the grazing-angle geometry, the acceptance angle of the SSB detector should be much smaller than the grazing angle. Otherwise the distribution of $\beta$ and with it the distribution of $[S]$ makes the depth resolution worse.

2.5 Energy-loss Straggling

The energy-loss process described in the previous section has a stochastic feature. The slowing down of the ion is accompanied by energy spreading which is called energy-loss straggling. For long path length, the energy distribution approaches a Gaussian distribution. The standard deviation $\Omega$ of the distribution for the high-energy limit was given by Bohr,$^{(15)}$ Equation (20)

$$\Omega_{\text{B}}^2 = 4\pi Z^2 Z_e e^4 N t$$

and has been extended to lower energies by many authors. A useful analytical formula was given by Lindhard and Scharff,$^{(16)}$ Equation (21)

$$\Omega^2 = \frac{\Omega_{\text{B}}^2}{\Omega_{\text{B}}^2} = L(\chi) = \begin{cases} 0.68\chi^{1/2} - 0.08\chi^{3/2} & \chi \leq 3 \\ 1 & \chi \geq 3 \end{cases}$$

where $\chi = (V/v_B)^2/Z^2$, $V$ is the ion velocity, and $v_B$ ($= 2.2 \times 10^6$ cm s$^{-1}$) the Bohr velocity. More refined models were developed by Bonderup and Hvelplund,$^{(17)}$ Chu,$^{(18)}$ and Besenbacher et al.$^{(19)}$

For compounds, an additive rule similar to Bragg's rule was proposed,$^{(18)}$ Equation (22)

$$\Omega^2(A_m B_n) = m \Omega^2(A) + n \Omega^2(B)$$

The contribution of the energy-loss straggling to the energy resolution is given by Equation (23)

$$\delta E_s^2 = 8 \ln 2 \left[ K^2 \Omega_{\text{in}}^2 + \Omega_{\text{out}}^2 \right]$$

where $8 \ln 2$ is a conversion factor from the standard deviation to the full width at half maximum, and $\Omega_{\text{in}}$ and $\Omega_{\text{out}}$ are the straggling in inward and outward paths. For mega-electron-volt H and He ions incident on layers $\leq 100$ nm, the straggling is small (e.g. $\Omega_B$ ca. 2.7 keV for He–Si at $t = 100$ nm) compared to the resolution of the SSB detector ($\delta E_d$ ca. 15 keV for mega-electron-volt He) and can be neglected in the obtainable depth resolution in the standard RBS. The contribution of the energy-loss straggling, however, increases with $t^{1/2}$ and the straggling sets a fundamental limit to the depth resolution at deeper layers.

3 STANDARD RUTHERFORD BACKSCATTERING SPECTROSCOPY

3.1 Apparatus

In the standard RBS, 1–4-MeV He ion beams and a SSB detector are commonly used. Although both the mass and depth resolutions are poorer for H ions than for He ions, H ions are sometimes used in RBS in order to analyze deeper regions. Ions generated by an ion source are accelerated by an electric field. The most widely used devices for the production of a mega-electron-volt ion beam are the Van de Graaff-type and Cockcroft-and Walton-type accelerators. The accelerated ions are analyzed by a magnet to eliminate contaminant ion species and to select the ion energy. The calibration of the analyzing magnet is usually done using resonant nuclear reactions. After passing the analyzing magnet, the ion beam is collimated by apertures to a size of ca. 1 mm and introduced to a scattering chamber where targets are mounted on a manipulator. The beam current is usually monitored by target current or a beam monitor system installed between the final aperture and the target. The typical beam current is of the order of 10 nA. For a channeling measurement, the beam divergence angle and the precision of the manipulator should be less than 1 mrad.

A SSB detector is installed inside the chamber to measure the energy spectrum of scattered ions. The SSB detector is basically a Schottky barrier diode. A reverse bias is applied to make a depletion region of the order of 100 µm which is greater than the range of the mega-electron-volt light ions. The electron-hole pairs created by the ion in the depletion region are swept by the high electric field and collected. The quantity of charge collected bears a linear relationship to the total energy spent to create electron–hole pairs (about 3.6–3.7 eV per electron–hole pair). The linearity between the collected charge and the ion energy is quite good for mega-electron-volt light ions. The signal from the detector is amplified
by a preamplifier and a linear amplifier and sent to a pulse-height analyzer (PHA). The PHA stores pulses of a given height in a given channel. The relation between the channel number and the ion energy can be calibrated by measuring ions of known energy, for example α particles from \(^{241}\)Am. It should be noted that the energy lost in the entrance window as well as the energy lost to nuclear scattering do not contribute to the pulse height. The equivalent thickness of the window is about 100 nm, which corresponds to about 30 keV loss for 1-MeV He. These effects are serious for heavy ions and must be taken into account in the conversion procedure from pulse height to ion energy, especially in the low-energy region.

### 3.2 Thin Film Analysis

An example of RBS spectrum for a high-\(T_c\) superconductor thin film deposited on a Si substrate is depicted in Figure 6.\(^\text{(20)}\) The film was prepared by ion beam sputtering of \(\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_7\). The peaks for Bi, Sr, Cu, and Ca are well separated and the oxygen peak can be clearly seen on top of the Si signal. The integrated counts \(Y_i\) for each element can be accurately determined. The areal density of element \(i\) is obtained from Equation (4) as

\[
n_i = N_it = \frac{Y_i \cos \theta}{(d\sigma/d\Omega)i \Delta \Omega}
\]

Although precise measurements of the ion energy \(E\), the scattering angle \(\theta\), the detector acceptance angle \(\Delta \Omega\), and the incident ion number \(Q\) are necessary to estimate the absolute areal density \(n_i\), an average stoichiometric ratio can be obtained without these values, Equation (25)

\[
\frac{N_i}{N_j} = \frac{Y_i (d\sigma/d\Omega) i}{Y_j (d\sigma/d\Omega) j} \approx \frac{Y_i}{Y_j} \left( \frac{Z_j}{Z_i} \right)^2
\]

The composition of the film shown in Figure 6 can be determined to be \(\text{Bi}_1\text{Sr}_{1.6}\text{Ca}_{0.9}\text{Cu}_{1.4}\text{O}_7\) using this equation.

In order to estimate the absolute areal density \(n_i\) using Equation (24), a standard sample implanted with a heavy element of a known areal density \(N_{\text{ref}}\) is sometimes used, Equation (26)

\[
n_i = N_it = \frac{Y_i (d\sigma/d\Omega)_\text{ref}}{Y_{\text{ref}} (d\sigma/d\Omega)_\text{ref}} N_{\text{ref}} \approx \frac{Y_i}{Y_{\text{ref}}} \left( \frac{Z^2_i}{Z^2_j} \right) N_{\text{ref}}
\]

where \(Y_{\text{ref}}\) is the yield of the standard sample measured under the same conditions. An alternative conventional method to estimate the absolute areal density is to make use of the signal of substrate material, Equation (27)

\[
n_i = N_it = \frac{Y_i \delta E_{\text{ch}}}{y_s [S]_j} N_i \frac{(d\sigma/d\Omega)_i}{(d\sigma/d\Omega)_s} \approx \frac{Y_i \delta E_{\text{ch}}}{y_s [S]_j} N_s \left( \frac{Z_j}{Z_i} \right)^2
\]

where \(y_s\) is the height of the energy spectrum at the leading edge of the substrate, \(\delta E_{\text{ch}}\) the corresponding energy for one channel, \(N_s\) the atomic density of the substrate, \((d\sigma/d\Omega)_s\), the differential cross-section of the substrate atom and \([S]_j\) the energy-loss factor for the substrate.

### 3.3 Depth Profiling

When the stoichiometry changes with depth, the variation of the composition can be determined from the RBS spectrum. The stoichiometry at a depth \(t\) can be derived from the corresponding yields of all compositional elements at \(t\), Equation (28). In Equation (28) \(F_i\) is the atomic fraction of element \(i\) at a depth \(t\).

\[
F_i = \frac{y_i[S]_i}{\sum_j y_j[S]_j} \left( \frac{d\sigma}{d\Omega} \right)_i \approx \frac{y_i[S]_i}{\sum_j y_j[S]_j} \left( \frac{d\sigma}{d\Omega} \right)_i \frac{Z_i^2}{Z_j^2}
\]

This procedure is not simple because the energy-loss factor \([S]_j\) is a function of the composition. For dilute concentrations of an impurity, the stopping power is simply determined by the matrix and the depth profiling...
NUCLEAR METHODS

1.1.2 1.3 1.4 1.5 1.6 1.7

0 1 2 3 4

Counts for Si (×10^−4)

2 MeV He Si(As)

Figure 7 RBS spectrum of 2-MeV He ions backscattered from Si implanted with 1.2 × 10^{15} As ions cm^{−2} at 200 keV. The arrows indicate the energy of ions scattered from surface Si and As atoms. (Reproduced by permission of Plenum Press from Mayer et al.)

is straightforward. Figure 7 shows an example of such an RBS spectrum for Si implanted with 1.2 × 10^{15} As ions cm^{−2} at 200 keV measured with 2-MeV He ions. There is a separated peak of As at ca. 1.55 MeV which corresponds to t ca. 150 nm. The width of the As peak at ca. 60 keV is much larger than the energy resolution of the SSB detector showing that the observed As peak profile reflects the actual As distribution in Si. The energy-loss factors for Si and As are calculated to be 44.3 and 46.0 eV Å^{−1} respectively. Using the peak yield of As, y_{As} = 250 and the Si yield at the corresponding depth, y_{Si} = 28000, the peak concentration can be calculated from Equation (28) as Equation (29)

\[ F_{As} \approx \frac{250 \times 46/33^2}{(250 \times 46/33^2 + 28000 \times 44.3/14^2)} = 0.0017 \]  

Note that the sensitivity of RBS can easily reach 100 ppm level for heavy elements.

The RBS spectrum shown in Figure 7 also provides a good example of how to estimate areal density of the implanted atoms using Equation (27). Using the total yield of the As peak \( Y_{As} = 3350 \) and \( \delta E_{ch} = 5 \text{ keV} \), the areal density of As is given by Equation (30)

\[ n_{As} \approx \frac{3350}{28000} \times \frac{5 \text{ keV}}{44.3 \text{ eV Å}^{-1}} \times 4.994 \times 10^{-2} \text{ Å}^{-3} \times \left( \frac{14}{33} \right)^2 = 0.12 \text{ Å}^{-2} \]  

The value obtained agrees well with the number of implanted As ions measured in the implantation procedure. This good agreement clearly shows the capability for quantitative analysis in RBS.

3.4 Computer Simulation

When the signals from different elements overlap in a spectrum, derivation of the target composition as a function of depth is not straightforward although a basic derivation can be obtained using Equation (28). A powerful approach to analyzing RBS spectra is by computer simulation. There are a number of computer simulation programs to analyze the RBS spectrum such as RUMP, GISA, and SCATT/HYPRA. In these programs, the target composition is changed until the calculated spectrum matches the measured spectrum. As with other inverse problems, this procedure may obtain a local minimum. Recently, a simulated annealing algorithm was successfully applied to the analysis of RBS spectra. It tends asymptotically to the absolute minimum rather than to a local minimum with any initial compositions. This allows fully automatic analysis without time-consuming human intervention. Figure 8 shows examples of the different steps of the fit to a RBS spectrum of a multilayered iron–cobalt silicide generated by the simulated annealing algorithm. The final result agrees reasonably well with the original spectrum with a simple initial composition (Figure 8a) generated automatically by the program.

3.5 Channeling Effect

The energy spectrum from a single crystal aligned with a low-index axis or plane parallel to the incident beam direction is very different from those discussed before. The ion experiences a series of correlated small angle collisions with crystal atoms and cannot approach to the atomic row or plane over a certain distance. This phenomenon, called channeling, drastically reduces the yield of Rutherford scattering. The analyzing procedures described in the previous sections cannot be applied to the RBS spectra measured under channeling conditions. In a simple RBS measurement, a single crystal target is usually rotated during measurement to avoid channeling effects.

Although the channeling is undesirable for RBS, it provides a unique method for studying lattice defects.
Channeling ions might stop channeling upon scattering by lattice defects (dechanneling) or even be directly backscattered from the defects (direct scattering). These effects depend on the structure of the defect. Impurity atoms, for example, may cause direct scattering depending on both the location of the impurity atom and the channeling axis as shown in Figure 9.\textsuperscript{(25)} The substituted atoms cannot be seen by channeling ions but the interstitial atoms may be seen by the ions channeling through particular channels. Thus the site of the impurity atom can be roughly determined by channeling measurements at several major axes. For more detailed information, the lattice site of the interstitial atom can be determined within an accuracy of 0.01 nm by measuring the incident-angle dependence of the backscattering yield from the impurity atoms around the channeling direction.

Other defects also cause dechanneling and the energy dependence of the dechanneling probability is different in each case, that is $\propto \sqrt{E}$ for dislocation, $\propto E^{0}$ for stacking fault, and $\propto E^{-1}$ for point defect.\textsuperscript{(26)} Thus the type of major defect can be determined by measuring the energy dependence of the dechanneling probability. Other useful applications of channeling are described in the literature.\textsuperscript{(27–29)}

### 3.6 Comparison to Related Techniques

The low-energy version of RBS is called ion scattering spectroscopy (ISS).\textsuperscript{(3)} Rare gas ions with energy of several kiloelectron volts and electrostatic analyzers are commonly used. ISS is sensitive to surface atoms because of the large neutralization probability of ions scattered from subsurface atoms and that is used extensively for compositional and structure analysis of surfaces. In order to study subsurface regions, the TOF technique is employed to measure energy spectra of both ions and neutral atoms. An alternative method is the use of alkali
metal ions for which the neutralization probability is small even for the ions scattered from the subsurface region.\(^{(30)}\)

The sensitivity of RBS is not sufficient for determination of trace elements. Particle-induced X-ray emission (PIXE) provides quantitative analysis of trace elements present at parts per million levels.\(^{(31)}\) Also see the article **PIXE (Particle-induced X-ray Emission)** in this publication. H ions of 1–3 MeV are used to produce inner-shell vacancies in target atoms. Characteristic X-rays emitted via refilling the inner-shell vacancies by outer-shell electrons are detected by an X-ray detector. Compared with the similar technique of electron probe microanalysis (EPMA), the background due to the bremsstrahlung is many orders of magnitude smaller and a sensitivity of better than 0.1 ppm is easily obtained for many elements in low-mass materials. Although the sensitivity of PIXE is excellent, PIXE does not have depth resolution.

Elastic Recoil Detection (ERD) is a similar technique to RBS.\(^{(32)}\) Also see the article **Elastic Recoil Detection Analysis** in this publication. In ERD, recoiled ions are detected instead of the scattered ions. While RBS is suitable for analysis of heavy elements, ERD provides quantitative depth profiles of light elements, especially hydrogen. Before the first introduction of ERD,\(^{(33)}\) nuclear reaction analysis (NRA) was predominantly used to measure depth profiles of light elements.\(^{(34)}\) Also see the article **Nuclear Reaction Analysis** in this publication. Nowadays, ERD is commonly used because of its simplicity and ease of use although the standard ERD has poorer sensitivity and depth resolution than NRA.

## 4 ADVANCED TECHNIQUES

### 4.1 Heavy Ion Rutherford Backscattering Spectroscopy

As was discussed in section 2.1, use of heavy ions improves mass resolution. Heavy ions also have an advantage of better depth resolution than light ions because the stopping power is proportional to the square of the ion charge. Figure 10 shows an example of heavy ion RBS (HIRBS) spectrum of a thin Y\(_1\)Ba\(_2\)Cu\(_3\)O\(_{7-x}\) film using 22-MeV \(^{12}\)C ions and a SSB detector.\(^{(35)}\) Although the energy resolution of the SSB detector is degraded for C ions, the separation of each element is perfect and, moreover, two copper isotopes, \(^{63}\)Cu and \(^{65}\)Cu, are clearly resolved, which is usually impossible in the standard RBS with megaelectron-volt He ions.

If the TOF technique is employed to measure the energy spectrum instead of the SSB detector, the energy resolution and thus both the mass and depth resolutions are improved considerably (typical energy resolution of TOF detectors is better than 1\%). Figure 11 depicts an example of a HIRBS spectrum (25 MeV \(^{35}\)Cl beam) of a 48 nm layer of GaAs capped by a 26 nm Pd layer on Si substrate measured with a TOF detector.\(^{(36)}\) The two Ga isotopes as well as several Pd isotopes are well-resolved.

Although the excellent mass resolution is clear in HIRBS, there are several disadvantages of HIRBS: (1) The cross-section deviates from the Rutherford formula particularly for heavy target elements. (2) Light
elements are less sensitive than standard RBS; in particular, elements lighter than the probe ion cannot be analyzed. (3) Irradiation of heavy ions causes significant radiation damage not only in targets but also in the SSB detectors.

4.2 High-resolution Rutherford Backscattering Spectroscopy

Improvement in the depth resolution up to atomic level has been tried by several groups. An overview of existing high-resolution spectrometers for IBA is given in the literature. It was shown that both a high-resolution spectrometer (energy resolution of ca. 0.1% is easily achieved for electrostatic or magnetic spectrometers) and a grazing-angle technique are essential for monolayer resolution in RBS. Figure 12 shows examples of HRBS spectra of PbTe (100) and PbTe (111) measured with a magnetic spectrometer. The arrows labeled Pb and Te indicate the energies of the ions elastically scattered from Pb and Te atoms. There are several peaks at ca. 285.5, ca. 283.3 and ca. 281.1 keV in Figure 12(a). These peaks correspond to the Pb atoms in the first, second, and third atomic layers, respectively. Note that even the ions scattered from the topmost atomic layer show inelastic energy loss because the electronic surface is outside the atomic surface. There are also small peaks at ca. 278 and ca. 275.8 keV corresponding to the Te atoms in the first and second layers. The yield ratio of the Pb peak to the Te peak is close to the cross-section ratio indicating that the PbTe (100) is stoichiometric. The spectrum of PbTe (111) shown in Figure 12(b) is basically the same as the PbTe (100) except for the yield of the first Pb peak. The yield of the first Pb peak is about 25% of the second and third Pb peaks and the inelastic energy loss for the first Pb peak (ca. 1 keV) is smaller than that for the first Te peak (ca. 2.1 keV). From these results, it can be concluded that the PbTe (111) surface is terminated by the Pb layer and the atomic density of the topmost Pb layer is reduced to about 25% of the bulk value.

Combination of heavy ions with a high-resolution spectrometer may provide better depth resolution. In addition to the large radiation damage, however, the charge-state distribution of the scattered heavy ions complicates the analysis because the scattered ions of all charge states cannot simultaneously be measured by the electrostatic or magnetic spectrometers. An optimal probe ion for HRBS has been discussed and
the sub-megaelectron-volt He ion was concluded to be the best one.\textsuperscript{(46)}

Disadvantages of HRBS are the relatively small acceptance angle $\Delta \Omega$ (typically less than 1 msr) and a narrow energy window of the spectrometer (typically several percent of the ion energy). These lead to a long acquisition time and possible radiation damage. Spectrometers with a wide acceptance angle and a wide energy window have been developed by several groups\textsuperscript{(47,48)} and not only a high-resolution spectrometer but also a high-resolution RBS system with a compact sub-megaelectron-volt ion accelerator are now commercially available.

### 4.3 Microprobe Rutherford Backscattering Spectroscopy

Finely focused high-energy ion beams turn ion beam spectroscopy into ion beam microscopy.\textsuperscript{(49)} Development of a high-energy ion microprobe was started as early as the late 1960s. There are more than 40 facilities which have high-energy ion microprobes. Magnetic quadrupole lenses are commonly used to form microprobes of the order of ca. 1 $\mu$m at a beam current of ca. 100 pA. In scanning the microprobe across a specimen and detecting a variety of ion-scattering processes, such as RBS, PIXE elastic recoil, nuclear reaction, and so on, microscope images are obtained. These images display features of the specimen that cannot readily be imaged by other techniques. The combination of the microprobe with RBS provides three-dimensional mapping of elements in the specimen.

Figure 13 shows an example of the RBS mapping and tomographic image of 1-$\mu$m-sized WSi$_x$ wiring lines.\textsuperscript{(50)} A beam of 300-keV Be\textsuperscript{2+} ions (beam size ca. 0.1 $\mu$m) was rastered over a 30 $\times$ 30 $\mu$m$^2$ area and RBS spectra were measured at 128 $\times$ 128 points. The mapping image is made with the W signal of the observed RBS spectra.

The tomographic image shows the cross-sectional image along the line shown in the mapping image, which is obtained by converting the each RBS spectrum to a depth distribution of W. The WSi$_x$ lines are clearly resolved in both the mapping and the tomographic images.

### 4.4 Light Element Analysis by Non-Rutherford Scattering

When the ion energy approaches the Coulomb barrier height of the target nucleus, the ion penetrates the Coulomb barrier and a compound nucleus in a highly excited state may be formed. If the incident energy of the ion matches one of the excited levels, the reaction probability is considerably changed and often enhanced. The excited compound nucleus thus produced may decay via re-emission of the incident particle. This phenomenon, called elastic resonance scattering, has a large cross-section sometimes several orders of magnitude larger than the Rutherford cross-section. Figure 14 displays an example of the non-Rutherford cross-section for $^4$He-$^16$O scattering as a function of the incident He energy.\textsuperscript{(51)} There are several resonances with enhancement factors of 100–200. Because the cross-sections for heavy elements remain Rutherford values in this energy region, the relative sensitivity for oxygen is improved by a factor of ca. 100. However, the cross-section varies in a very complicated manner with energy and also with the scattering angle. The analysis of energy spectra has to be performed with care. There is an energy region, 8.3–8.9 MeV, where the cross-section varies slowly. Using this energy region the analysis of oxygen is as simple as standard RBS with an enhancement factor of about 35.

![Figure 14](image-url)

**Figure 14** Measured 170° laboratory cross-sections for $^4$He-$^16$O expressed in terms of the Rutherford cross-sections.

(Reproduced by permission of Elsevier Science B.V. from Cheng et al.\textsuperscript{(51)})
A sharp and isolated resonance is seen at $E_R = 3.045 \text{ MeV}$. When the energy of the incident He ions is larger than $E_R$, the resonance occurs at a certain depth where the ion energy matches $E_R$ after energy loss in the incoming path, that is, only the oxygen at a certain depth can be seen by the resonance. Thus a sharp resonance can be used for depth profiling of oxygen by sweeping the incident ion energy. Other examples of sharp resonances used in non-RBS are the 4.265 MeV resonance in the $^4\text{He}/^6\text{Li}$ cross-section and 2.525 MeV resonance in the $^1\text{H}/^9\text{Be}$ cross-section. Useful data on non-Rutherford cross-sections for H and He incident ions are compiled in the literature.\textsuperscript{52}

Chemical Analysis by Nuclear Methods: Introduction ● Elastic Recoil Detection Analysis ● Nuclear Reaction Analysis ● Particle-induced γ-Ray Emission ● PIXE (Particle-induced X-ray Emission)

**REFERENCES**

It is possible to determine many gases and vapors in workplace air through the use of direct-reading instruments. However, these instruments are often expensive, and not suited to personal monitoring as required by standards and regulations. They also may be insufficiently selective to monitor atmospheres contaminated by a mixture of components, or insufficiently sensitive to determine the low concentrations of, for example, regulated carcinogens. A more common technique is to remove a sample of air for subsequent analysis, typically in a laboratory, but sometimes in the field. This article covers sampling techniques for the determination of gases and vapors in air. It also covers recovery techniques that are applicable to the laboratory. It is not possible to completely divorce these subjects as the selection of sampling method is often dependent on the choice of recovery technique, and vice versa. Taking a sample of air improves the sensitivity of analysis, as well as integrating the result over the time-period of sample collection. Exposure limit (EL) values are normally given as time-weighted average concentrations over work-shifts or shorter periods. It is possible in most cases to choose a sampling method to cover a full work-shift with a single sample. By far the commonest technique is to concentrate the sample by collecting the contaminants of interest using a solid or liquid sorbent, where the mechanism of collection is adsorption, chemical reaction, or solution. The collection procedure involves either pulling air through the sorbing medium (active sampling) or allowing the molecules to diffuse to the medium under certain conditions (passive, or diffusive, sampling).

The commonest technique for recovery is solvent desorption. An aliquot of the solution is then presented for analysis. For volatile organic compounds (VOCs), the commonest technique is to use a charcoal sorbent medium contained in a tube, through which air is drawn, followed by desorption using carbon disulfide, either alone or mixed with other solvents. Probably more than 75% of workplace air samples for VOCs are taken this way. Thermal desorption, using heat to release the sampled VOCs, rather than a solvent, is of rapidly growing importance because of its higher sensitivity. The selection of sorbent is more critical, and most recent protocols are using multiple beds of different sorbents. Whole-air samples in polymer bags have been taken for industrial monitoring of permanent gases, whereas whole-air samples in passivated metal canisters have been used commonly in
ambient air monitoring of VOCs. Similar, but smaller, metal canisters may also be used in future for industrial hygiene work. Industrial hygiene air sampling will exist for as long as chemicals are used in the workplace, to determine the existence of hazards and the extent of risks, as well as to ensure the effectiveness of engineering controls. In many countries, the use of air sampling is a requirement of health and safety programs in order to compare workers’ exposures to regulatory guidelines or legal limits.

1 INTRODUCTION

This article discusses the sampling and recovery of gases and vapors commonly found in the workplace environment. Many of these techniques are equally applicable to indoor or ambient-air monitoring outside of the workplace. It is limited to descriptions of sampling methods for on-site or subsequent laboratory analysis. It does not, therefore, include any discussions of direct-reading instruments or laboratory analytical procedures (other than sample recovery), which can be found in the appropriate related articles.

2 SELECTION OF SAMPLING DEVICES AND MEASUREMENT METHODS

There are two basic methods for collecting gas and vapor samples. In one, called whole-air sampling, an actual sample of contaminated air is taken in a flask, bottle, bag, or other suitable container. In the other, called sorbent sampling, gases or vapors are removed from the air and concentrated by contact with a sorbing medium.

The first method is often used for the collection of instantaneous or short-term (grab) samples, usually within a few seconds or a minute, but the method is easily adapted to sampling over longer periods. Many direct-reading on-the-spot devices also involve grab sampling. Grab sampling is of questionable value when the contaminant or contaminant concentration varies with time and a time-weighted average exposure is desired. In such circumstances, integrated sampling is used instead, and the most popular method used in occupational hygiene today is sorbent sampling. The gas or vapor is extracted from air and concentrated by (a) dissolution in a sorbing liquid, (b) reaction with a sorbing solution (or reagent therein), or (c) collection onto a solid sorbent. Any of these methods can be combined with analytical reagents to provide an on-site determination. For each method the collection efficiency should be accurately known and should be close to 100%. For samples analyzed by laboratory techniques sample recovery efficiency and storage stability should also be known.

There are thus frequently many alternative approaches to the determination of gases and vapors, and the best one will depend on the circumstances.

Factors that will need to be taken into account include:

1. the measurement task;
2. the concentration to be determined;
3. the time resolution required;
4. selectivity to the target gas or vapor and sensitivity to interfering gases and vapors;
5. bias, precision and overall uncertainty required;
6. susceptibility of the sampler to environmental factors;
7. fitness for purpose, such as weight, size, durability, etc. (and especially the suitability of the equipment for personal monitoring);
8. training requirements for the reliable operation, maintenance and calibration;
9. the total cost of purchase and operation, including calibration and maintenance;
10. compliance with the performance requirements of appropriate national regulations;
11. conformity to the user’s quality system.

Having established the requirements, the next step in the selection of a sampling device and analytical procedure is to search the available literature. Primary sources are the compendia of methods recommended by the regulatory authorities or governmental agencies in Europe:

- the UK Methods for the Determination of Hazardous Substances;
- the German Analytische Methoden and BIA Arbeitsmappe Messung von Gefahrstoffen;
- the Swedish Principer och Methoden;

Secondary sources are published literature references in, for example, the Analyst, the Journal of Environmental Monitoring, the Annals of Occupational Hygiene, Staub, Reinhalung der Luft, the American Industrial Hygiene Association Journal, or Applied Occupational and Environmental Hygiene. Further valuable resources include the Methods Exchange Network of the American Industrial Hygiene Association (AIHA) and standards published by the American Society for Testing and Materials (ASTM; see section 8).
If a published procedure is not available, then one can be devised from theoretical considerations. However, its suitability must be established experimentally before application. Protocols for these experimental evaluations are available from the government agencies and standards organizations mentioned above. The final stage is to review the performance characteristics of the available methods against the selection criteria already established. Important information on the performance characteristics (items 5 and 10 above) of devices or procedures can be obtained from various sources. These include:

- the manufacturer’s instructions for use;
- published commercial technical information;
- technical and research publications;
- national and international standards (see section 8);
- user groups.

3 WHOLE-AIR SAMPLERS

3.1 Methods of Sampling and Analysis

Whole-air samplers are containers of varying capacity and configurations. They can have a rigid construction (typically metal), in which case, the internal pressure of the container is reduced, either to near zero (<0.1 mbar) or to a known absolute pressure, and sampling takes place by filling through a critical orifice. If the container size is carefully matched with the size of the critical orifice, samples of various volumes can be obtained over different time-periods. It is possible to obtain sufficient sample for replicate analyses from a container whose volume is low enough (200–600 mL) for the container to be worn as a personal sampler. Such a container can be filled over long time periods with the appropriate choice of critical orifice. For example, a sampling rate of 0.4 mL·min⁻¹ will two-thirds fill a 300 mL container over an 8-hour work-shift. As the vacuum is depleted the orifice will become subcritical and the subsequent rate of fill nonlinear. Two-thirds fill is a typical limitation of the linear range of critical-orifice controllers, although some are now available with modifications so that the fill-rate remains linear with only small pressure differences. Fine filters are required to ensure the flow controllers are not blocked by particles. This method has the advantages that a personal sampling pump is not required and that the containers normally can be re-used.

Alternatively, the containers can be of flexible plastic, in which case the internal volume is close to zero when sampling begins, and sample is either fed into the container, or drawn in by a vacuum applied to the exterior of the container. The former technique can lead to bias either through contamination of the sample or loss from the sample during passage through the sampling pump. One manufacturer supplies a sampling pump specifically designed to minimize these biases. The latter technique involves a pump and a rigid box that can be evacuated and the assembly is too cumbersome for personal sampling.

Both types of containers are generally removed to a laboratory for analysis, although it is possible to achieve field readability if the proper equipment and direct-reading instrument are available. The NIOSH (US) National Institute for Occupational Safety and Health has published several methods for the field determination of vapors after collection with sampling bags. In the laboratory, the containers can be analyzed by direct injection into the analytical device. For sampling bags this is usually by withdrawing an aliquot through a septum fitting on the bag with a gas-tight syringe. For rigid containers the procedure is more complex. Typically, the pressure within the container is measured and the container is then overpressurized with clean gas (air, nitrogen, or helium) and the pressure measured again. From the pressure difference the dilution of the sample can be determined. An aliquot of the sample is then bled into a gas-sampling valve and passed to the analytical device. This procedure has the advantage of allowing several analyses of the same sample, but the disadvantage of diluting it. It is also possible to overpressurize the sample in the field, using a pump. However, if the water vapor partial pressure within the canister exceeds its saturation vapor pressure then water vapor condenses on the canister wall. This can have a marked effect on the recovery of polar compounds and on the analysis because the amount of water vapor entering the gas chromatography (GC) column will vary as sample is withdrawn from the container.

An alternative procedure for the analysis of canisters is to pump out the entire contents of the sample through a trap (cold trap, sorbent trap, or a combination) and to analyze the contents of the trap. This only allows a single shot at the analysis, but eliminates the dilution factor, and the problem of moisture condensation within the can, as the water will be dealt with at the focusing stage.

3.2 Canisters

Glass containers originally used to collect samples have been largely superseded by stainless steel containers that have been specially treated to reduce sorption effects. Such treatments include electropolishing (removal of free surface iron), the SUMMA® process (deposition of mixed nickel/chromium oxide), and SilicoSteel® lining (deposition of fused silica layer). Electropolished canisters are seldom seen today. SUMMA® canisters are the most widespread, but they show poor stability for some reactive compounds, and give poor recoveries, especially for
polar organic compounds, at low humidities. Water can be injected into the can to alleviate this problem. Fused silica-lined cans show greater stability for some reactive compounds and better recovery for polar compounds and are becoming very popular. All types of canister have been used extensively for collecting trace organic gases in ambient air sampling, but their potential advantages have only recently been recognized in occupational sampling. Advantages over the traditional pump/sorbent method include:

- applicability to low-molecular-weight compounds (e.g. C₁ and C₂ hydrocarbons, permanent gases) and some reactive compounds (e.g. reduced sulfur gases);
- minimal interference from ozone (inside the container ozone has a short life-time because of autoreaction);
- independence from batteries (e.g. can be used in cold climates).

The size and weight of containers is greater than the micropumps used for low flow-rate sampling, but not much greater than the larger personal pumps used for sampling aerosols. The cost of container plus orifice controller is equivalent to that of a high-end sampling pump. Larger containers are held in a harness suspended from the workers' shoulder, smaller containers may be equipped with a belt-clip.

A recent study has shown some significant under- and overestimations of certain compounds by the canister method compared to a continuous cycling gas chromatograph used for ambient air analysis.

### 3.3 Flexible Plastic Containers

Plastic bags are used to collect air samples and prepare known concentrations that can range from parts per billion to more than 10% by volume in air. The bags are commercially available in sizes up to 250 L. However, 1–15 L bags are the most useful.

These bags are constructed from a number of materials, including polyester, polyvinylidene chloride, Teflon®, aluminized Mylar®, or other fluorocarbons (e.g. Tedlar®). Tedlar® bags are the most popular. Bags have the advantages of being light, nonbreakable, inexpensive to ship, and simple to use. However, they should be used with caution as many factors affect precision and accuracy. Storage stability is probably the most critical factor affecting the use of bags. Instability may be due to permeation through the material of the bag, adsorption by the bag or fittings and/or reaction with other sampled components. Permeation through the bag is a function of the ratio of bag surface area to filled volume, the nature and thickness of the material, and the temperature. Although permeation is relatively rapid for permanent gases it is not the main source of long-term losses for less-VOCs. Losses of these compounds can be relatively rapid (half-life of hours) or slow (half-life of days) and depend more on the nature of the bag material and fittings (for example, many compounds are more stable in the presence of polypropylene fittings than stainless steel fittings).

Photochemical reactions have been observed inside clear bags, and opaque bags are often recommended for reactive compounds. An example of a popular sampling method using Tedlar® bags is the method for reduced sulfur gases published by the National Council for Air and Stream Improvement (NCASI) in the USA.

Plastic bags should be tested before they are used. Such testing should be done under ambient conditions that approximate those of the sampling environment. Some general recommendations are available in the published literature for the use of such bags for air sampling. A good review of specific applications up to 1967 is Schuette. Other specific applications have been discussed. Posner and Woodfin made a useful systematic study of five bag types and six organic vapors; they conclude that Tedlar® bags are best for short-term sampling, whereas aluminized Mylar® bags are better for long-term storage prior to analysis. Storage properties, decay curves, and other factors, however, will vary considerably from those reported for a given gas or vapor because sampling conditions are rarely identical. Each bag, therefore, should be evaluated for the specific gas or gas mixture for which it will be used. In theory, these bags are reusable, but caution must be exercised as memory effects are common, and small holes or other leaks can appear after even a single use. Bags should not be filled to bursting, and filled bags should not be transported in depressurised aircraft holds. In addition, before transporting hazardous atmospheres in any kind of containers it is necessary to check whether the containers comply with transportation safety regulations.

### 4 ACTIVE SORBENT SAMPLERS

#### 4.1 Sampling Pumps

Except for evacuated canisters (described in section 3) and diffusive samplers (described in section 5), sampling devices are used in conjunction with a sampling pump and air-metering device. To avoid contaminating the metering device and pump, these are usually placed downstream of the sampler during the sampling period. However, because many samplers introduce back-pressure, the sampling train should be precalibrated by the use of an external flow-meter upstream of the sampling head.

There are a large number of manufacturers of sampling pumps, although the mechanisms are rather similar and
not far removed from the fish-tank pumps they were developed from. Typically, personal sampling pumps operate through movement of a piston or diaphragm, and often contain some form of surge or pulsation dampener to ensure even flow (within 5% of specification). A feed-back circuit may be included to cause pumps to speed up or slow down in response to back-pressure changes. Although the latest generation of pumps has sophisticated means to measure the flow, government regulations normally require the flow to be checked before and after sampling (and the final result to be within 5% of the initial reading) using a standard method such as a bubble flow-meter. Periodic calibration during the sampling period is recommended for most accurate results. Some form of visual flow-fault indicator is often included to alert the wearer to failure of the sampling train. Most pumps, whether piston or diaphragm, can be assumed to deliver a fixed volume that does not change with temperature and pressure. However, that is not always true for the calibration device. Whereas bubble flow-meters also have a fixed volume, the calibration of a rotameter depends on air density and, therefore, on temperature and pressure. A pump should be calibrated using a bubble flow-meter for most accurate results without need of correction.

Since the early 1970s the size, weight and noise emission of pumps has been reduced to the point of being an equivalent burden to the worker as one of today’s cellular telephones. Sampling pumps are sold at a moderate cost, practically insignificant when amortized over a large number of samples, and when compared to the cost of analysis of those samples. Added to this cost, however, is the requirement for maintenance and calibration. Using an occupational hygiene professional only for pump calibration is a possibly unnecessary extra expense to a sampling program.

4.2 Liquid Absorbers

The sorption theory of gases and vapors from air by solution, as developed by Elkins et al., assumes that gases and vapors behave like perfect gases and dissolve to give a perfect solution. The concentration of the vapor in solution is increased during air sampling until an equilibrium is established with the concentration of vapor in the air. Sorption is never complete, however, because the vapor pressure of the material is not reduced to zero but is only lowered by the solvent effect of the sorbing liquid. Some vapor will escape with continued sampling, but it is replaced. Continued sampling will not increase the concentration of vapor in solution once equilibrium is established.

According to formulas developed by Elkins et al., and verified by Gage in his experiments with ethylene oxide, the efficiency of vapor collection depends on (a) the volume of air sampled, (b) the volume of the sorbing liquid, and (c) the volatility of the contaminant being collected. Efficiency of collection, therefore, can be increased by cooling the sampling solution (reducing the volatility of the contaminant), increasing the solution volume by adding two or more bubblers in series, or altering the design of the sampling device. Sampling rate and concentration of the vapor in air are not primary factors that determine collection efficiency.

Sorption of gases and vapors by chemical reaction depends on the size of the air bubbles produced in the bubbler, the interaction of contaminant with reagent molecules, the rapidity of the reaction, and a sufficient excess of reagent solution. If the reaction is rapid and a sufficient excess of reagent is maintained in the liquid, complete retention of the contaminant is achieved regardless of the volume of air sampled. If the reaction is slow and the sampling rate is not low enough, collection efficiency will decrease.

Four basic sorbers used for the collection of gases and vapors are simple gas-washing bottles, spiral and helical sorbers, fritted bubblers, and glass-bead columns. Their function is to provide sufficient contact between the contaminant in the air and the sorbing liquid.

Petri, Dreschel, and midget impingers are examples of simple gas-washing bottles. They function by applying a suction to an outlet tube, which causes sample air to be drawn through an inlet tube into the lower portion of the liquids contained in these absorbers. They are suitable for collecting nonreactive gases and vapors that are highly soluble in the sorbing liquid. The sorption of methanol and butanol in water, esters in alcohol, and organic chlorides in butyl alcohol are examples. They are also used for collecting gases and vapors that react rapidly with a reagent in the sampling media. High collection efficiency is achieved, for example, when toluene diisocyanate is hydrolyzed to toluene diamine in Marcali solution. Hydrogen sulfide reaction with cadmium sulfate and ammonia neutralized by dilute sulfuric acid are other examples.

4.3 Solid Sorbents

Solid materials will remove gases and vapors from air with which they are in contact. This is a result of the physical forces of adsorption (particularly the London dispersion force of the Van der Waals interactions) or it may be a result of the stronger attraction of hydrogen bonding, or even of complete chemical reaction. In the case of physical adsorption, the strength of the adsorption and the capacity of the adsorbent are related to its surface area and porosity, as well as to the chemical nature and polarizability of both the surface and the adsorbed
molecules. However, even such relatively nonporous materials as glass beads and stainless steel surfaces are able to adsorb significant numbers of molecules, and this is the cause of sample losses in some systems. In order to obtain sufficient molecules for analysis it is necessary to effectively trap all of the contaminant molecules in samples of up to several liters of air, and preferably in a small quantity of sorbent that can be deployed conveniently for personal sampling. This requires a sorbent with a relatively large surface area (from 10 to above 1000 m² g⁻¹).

The sorption capacity of a sampler, i.e. the volume of air that can be collected without loss of contaminant, depends on the sampling rate, the quantity of sorbent, the sorbent surface area, the density of active sites and bulk density, the volatility of the contaminant, and the concentration of contaminant in the air. Sampling pumps are limited to an accurate lower flow-rate of around 20 mL min⁻¹, resulting in a 10 L sample over 8 h. For many organic vapors, this sample volume can be collected even at flow-rates up to 1 L min⁻¹, without significant loss using glass tubes containing 100–400 mg sorbent in a primary adsorptive layer. A secondary back-up layer, typically containing half the sorbent of the primary layer is included to detect breakthrough of sampled material. A breakthrough of more than 20% of the total sample collected found in the back-up section indicates that some of the sample probably was lost. Optimum sample volumes are found in validated procedures.²⁸,⁵

It is normally best to refer to an established procedure for proper sampling rates and air sample volumes. In the absence of such information, breakthrough experiments must be performed before field sampling is attempted. Normally, these experiments are conducted using dynamic standard atmospheres prepared at twice the EL or threshold limit value (TLV®) to give a suitable margin of safety to the measured breakthrough volume.²⁸ In addition, such tests should be performed at high humidities, or else a substantial correction factor should be used to account for the effects of atmospheric water vapor. Some sorbents such as carbon beads for methanol, 2,4-dinitrophenylhydrazine-coated silica gel for formaldehyde, and sulfuric acid-coated carbon beads for phosphate are less effective at low humidity, but this is less commonly encountered. Several methods for testing the collection efficiency of a sorbing device are available:

- by sampling from a dynamic standard atmosphere or from a gas-tight chamber or tank containing a known gas or vapor concentration (as mentioned);
- by series testing where enough samplers are arranged in series so that the last sampler does not recover any of the test gas or vapor;

- by comparing results obtained with a device known to be accurate;
- by introducing a known amount of gas or vapor into a sampling train containing the absorber being tested.

In addition to the collection efficiency it is also necessary to define the recovery efficiency and, as this frequently varies with chemical loading on the sorbent, the procedure normally involves dosing the sampler with varying quantities of the analyte. This experiment is repeated after allowing the chemicals to equilibrate with the sorbent for the longest period of practical storage time prior to analysis (2–3 weeks).

After the procedure has been validated, field sampling may be performed. Immediately before sampling, the ends of the sorbent tube are broken, rubber or Tygon® tubing is connected to the back-up end of the sorbent tube, and air is drawn through the sampling train with a calibrated pump. A personal breathing zone or area sample may be collected. The duration of the sampling may be several minutes or up to 8 h or longer, depending on the information desired. When sampling is completed, plastic, rather than rubber, caps are placed on the ends of the tube.

4.3.1 Choice of Desorption Procedure

An early drawback to using sorbent tubes for air sampling of organic compounds was the difficulty in recovering samples for analysis. Although the weight-difference before and after sampling could be used as an estimate of the pollution, this is a very crude and nonselective measure. A solvent can be used to displace the collected compounds, and an aliquot of the solvent can then be injected into a chromatograph to separate the components followed by a detector to quantify them. The ideal solvent should consist of small molecules to enable penetration of pores in the nanometre size range, a high heat of adsorption to ensure release of the collected compounds, and good solvating power for a wide range of organic compounds. In addition, it should be easily separated from the chemicals of interest, and not interfere with their analysis.

Alternatively, collected compounds can be released by the application of heat by a procedure known as thermal desorption. Unfortunately, some sorbents exhibit catalytic properties at high temperatures, and some tend to adsorb water from the air, which render them less suitable for thermal desorption, but other sorbents are available that are much more useful. Almost any single vapor could be collected on a sorbent and removed using either desorption procedure. The final choice is quite complex and depends on many factors, not least of which is the availability of the equipment.
4.3.1.1 Solvent Desorption  The most frequently used solvent for liquid desorption, especially from charcoal (see section 4.3.2.1), is carbon disulfide. Carbon disulfide has many advantages. It penetrates even the smallest pores of charcoal and has a very high heat of adsorption. It is a good solvent for nonpolar compounds, although not so good for polar compounds. It does not react with most displaced compounds (except amines). Best of all, it is easily separated from most other compounds and has a reduced response to flame ionization detection (FID), although remnant ions will quench the response of closely eluting chlorinated hydrocarbons. Carbon disulfide does not always completely remove all compounds from charcoal. Recovery varies for each chemical and for each batch of charcoal used. The extent of individual recoveries must be determined experimentally and a correction for desorption efficiency applied to the analytical result.29 Over a narrow range of analyte concentrations, as used in the NIOSH validations,30 this desorption efficiency is essentially constant, but it may vary widely over larger concentration ranges, particularly for polar compounds.31,32 Desorption efficiency can also be affected by the presence of water vapor and other contaminants.33–35 The NIOSH3 recommends that methods be used only where the desorption efficiency is greater than 75%; ideally, it should be greater than 90%. The recovery of polar compounds may be improved by the addition of a polar modifier (typically an alcohol) or by the use of an alternative solvent such as a mixture of methylene chloride and methanol, or dimethylformamide (either alone or in combination with carbon disulfide). Dimethylformamide has the advantage of being miscible with both carbon disulfide and any collected water. Although it has a significant FID response, because of its high boiling point (172 °C) and high polarity, it elutes in a region of the chromatogram with little else of interest, and thus does not interfere with most analyses.

The practical desorption step in charcoal analysis is also critical because, upon the addition of carbon disulfide to charcoal, the initial heat of reaction may drive off the more volatile components of the sample. This can be minimized by adding charcoal slowly to precooled carbon disulfide. Another technique is to transfer the charcoal sample to vials lined with Teflon® septum caps and to introduce the carbon disulfide with an injection needle. The sealed vial will prevent the loss of any volatilized sample. Headspace analysis is then possible.

It should be emphasized that carbon disulfide is a highly toxic solvent that produces serious effects on the cardiovascular and nervous systems. Care should be exercised in handling the solvent, and the analytical procedure should be performed in a well-ventilated area. Dimethylformamide has a very low vapor pressure and therefore presents less of a hazard from breathing, but there is also potential toxic hazard from dermal exposure.

Solvents for other sorbents are discussed under the sorbent type. Solvent desorption has the principal disadvantage of diluting the sample before analysis, but the principal advantage of allowing more than one analysis per sample. Solvent desorption requires only normal laboratory glassware and chemicals. It can be automated to handle high sample throughput.

4.3.1.2 Thermal Desorption  Because of the high toxicity and flammability of carbon disulfide and the labour-intensive nature of the solvent desorption procedure, a useful alternative is to desorb the collected analyte thermally.36–38 Except in a few cases, this is not practical with charcoal as sorbent because the temperature needed for desorption (e.g. 300 °C) would result in some catalytic decomposition of the analytes. Weaker sorbents are used instead, so larger tubes are required as more sorbent is required for efficient collection; usually 200–500 mg of sorbent, depending on type. Desorption can be made fully automatic, and analysis is usually carried out by GC. Some desorbers also allow automatic selection of sample tubes from a multiple-sample carousel. The whole sample can be transferred to the gas chromatograph, resulting in greatly increased sensitivity compared with the solvent desorption method. Alternatively, some desorbers allow the desorbed sample to be held in a reservoir from which aliquots are withdrawn for analysis, but then the concentrating advantage is reduced.

Because the least volatile components of the atmosphere are collected at the front of the tube, and the most volatile components penetrate further, sorbents tubes are normally desorbed in the reverse direction from sampling, or in back-flush mode. This becomes very important when combinations of sorbents are used in the tube. Although the sample could, in theory, be entered directly into the chromatograph upon desorption, this is rarely done in practice as broad peaks would result. Secondary trapping involves either adsorption on a smaller, secondary sorbent bed, or cryofocusing, or a combination of both. The equipment is expensive and represents a significant add-on to the standard cost of a gas chromatograph.

The main disadvantage of thermal desorption directly with an analyzer is that it is essentially a one-shot technique; normally, the whole sample is analyzed. This is why many such methods are linked to mass spectrometry. However, with capillary chromatography, it is usually possible to split the desorbed sample before analysis and, if desired, the vented split can be collected and reanalyzed.39 Alternatively, the desorbed sample can be split between two capillary columns of differing polarity.40
Desorption efficiency is usually 100% for the majority of common solvents and similar compounds in a boiling range of approximately 50–250 °C. However, if a wide boiling range is to be covered, more than one sorbent may be required. Thus, gasoline may be monitored by a Chromosorb 106 tube and carbon tube in series. Extensive lists of recommended sampling volumes and minimum desorption temperatures for Tenax® and other sorbents are given by Brown and Purnell[38] and the UK Health and Safety Executive (HSE) Method MDHS (methods for the determination of hazardous substances) 72.[43]

Thermal desorption has been adopted as a (non-exclusive) recommended method for the determination of VOCs in the UK,[1] Germany,[2] and the Netherlands,[44] but it is less widely accepted elsewhere. The NIOSH[5] has relatively few methods based on thermal desorption (compared to those which use solvent desorption). The USEPA[7] has a number of methods based on thermal desorption and mass spectrometry for the lower concentrations found in ambient and indoor air. As regulated limits for occupational exposure reach 1 ppm or less (e.g. benzene, acrylonitrile, vinyl chloride, 1,3-butadiene, ethylene oxide, etc.) the potential of thermal desorption for analysis of a concentrated sample without dilution becomes more appealing.

4.3.2 Solid Sorbents Used with Solvent Desorption

4.3.2.1 Activated Charcoal  Charcoal is an amorphous form of carbon formed by partially burning wood, nutshell, animal bones, and other carbonaceous materials. A wide variety of charcoals are available; some are more suitable for liquid purification, some for decolorization, and others for air purification and air sampling. Ordinary charcoal becomes activated charcoal by heating it with steam to 800–900 °C. During this treatment, a porous, submicroscopic internal structure is formed that gives it an extensive internal surface area, as large as 1000 m² g⁻¹ charcoal. This greatly enhances its sorption capacity. Activated charcoal is an excellent sorbent for most organic vapors. During the 1930s and 1940s, it was used in the then well-known activated charcoal apparatus[24] for the collection and analysis of solvent vapor. The quantity of vapor in the air sample was determined by a gain in weight of the charcoal tube. Lack of specificity, accuracy, and sensitivity of the analysis and the difficult task of equilibrating the charcoal tube, however, discouraged use. Renewed interest in activated charcoal as a sorbent for sampling organic vapors appeared in the 1960s.[29,45,46] The ease with which carbon disulfide extracts organic vapors from activated charcoal and the capability of microanalysis by GC are the reasons for its current popularity. Air sampling procedures using activated charcoal are widely used by industrial hygienists[47–49] and form the basis of the majority of the official analytical methods for VOCs recommended by the HSE,[1] NIOSH[5] and OSHA (Occupational Safety and Health Administration).[6]

Analytical information on selected NIOSH procedures is given in Table 1. In general, the NIOSH procedures use a 100 mg charcoal tube (with 50 mg back-up), but very volatile analytes may require a larger tube. The NIOSH studies showed that the charcoal tube method is generally adequate for hydrocarbons, halogenated hydrocarbons, esters, ethers, alcohols, ketones, and glycol ethers that are commonly used as industrial solvents. Compounds with low vapor pressure and reactive compounds (e.g. amines, phenols, nitro compounds, aldehydes, and amines) generally have low desorption efficiencies from charcoal and require alternative sorbents such as silica gel or porous polymers for collection, or alternative reagent systems for recovery. Compounds containing a carbon–carbon double bond (e.g. vinyl compounds and acrylates) often show recoveries dependent on loading, which is partially a function of the presence of active sites of strong adsorption on the carbon surface. These sites may be stabilized by the presence of a free-radical inhibitor such as hydroquinone or tert-butyl catechol.

Inorganic compounds, such as ozone, nitrogen dioxide, chlorine, hydrogen sulfide, and sulfur dioxide, react chemically with activated charcoal and cannot be collected for analysis by this method. Even for substances recommended for sampling on charcoal, this sorbent may not always be ideal. Reference
to Table 1 will indicate that carbon disulfide is the recommended desorption solvent for nonpolar compounds, whereas a variety of desorption cocktails are required for the more polar compounds. Difficulties arise, therefore, when sampling mixtures of polar and nonpolar compounds because each will give poor recoveries with the other’s desorption solvent. One option is to use a two-phase carbon disulfide–water mixture for desorption with analysis of both phases.\(^{50}\) Several alternative and more universal solvents have been investigated,\(^{51–52}\) but

<sup>r</sup> Two tubes 100/50 + 100/50 mg.

<sup>s</sup> 600 + 400 mg tube.
none of these has achieved wide recognition. In such circumstances, it may be necessary to take two samples and desorb each one with a different solvent.

4.3.2.2 Silica Gel  Silica gel is an amorphous form of silica derived from the interaction of sodium silicate and sulfuric acid. It has some advantages over activated charcoal for sampling certain gases and vapors. Polar contaminants, including alcohols, amines, amides, and phenols are more easily removed from the sorbent by polar solvents such as water, methanol or acetonitrile, and some inorganic substances, including acid gases and vapors (e.g. HF, HCl, formic and acetic acids) for which charcoal is unsuitable can be collected.

One disadvantage of silica gel is that it will adsorb water. Silica gel is electrically polar, and polar substances are preferentially attracted to active sites on its surface. Water is highly polar and is tenaciously held. If enough moisture is present in the air or if sampling is continued long enough, water will displace organic solvents (which are relatively nonpolar in comparison) from the silica gel surface. With water vapor at the head of the list, compounds in descending order of polarizability are alcohols, aldehydes, ketones, esters, aromatic hydrocarbons, alkenes, and alkanes. It is obvious, therefore, that the volume of moisturized air that can be effectively passed over silica gel is limited.

In spite of this limitation, silica gel has proved to be an effective sorbent for collecting many gases and vapors. Even under conditions of 90% humidity, relatively high concentrations of benzene, toluene, and trichloroethylene are quantitatively sorbed on 10 g of silica gel from air samples collected at the rate of 2.5 L min⁻¹ for periods of at least 20 min or longer. Under normal conditions, hydrocarbon mixtures of 2–5 carbon alkanes, low-molecular-weight sulfur compounds (H₂S, SO₂, mercaptans), and alkenes concentrate on silica gel at dry ice–acetone temperature if the sample volume does not exceed 10 L. Significant losses of ethylene, methane, ethane, and other light hydrocarbons occur if the sampling volume is extended to 30 L.

4.3.2.3 Polymeric Sorbents  A variety of organic polymers have been used for sample collection followed by solvent desorption. The commonest are polymers derived from styrene, often with admixture from similar aromatic compounds such as ethyl vinyl benzene or divinyl benzene. These can be obtained from several different manufacturers, and are available under the manufacturers’ trade names (e.g. Amberlite®, Chromosorb®, Porapak®, and Hayesep®). These are generally either microporous (surface areas of 600–800 m² g⁻¹), such as Amberlite® XAD-4, Chromosorb 106®, Porapak Q® or Hayesep D®, or mesoporous (surface areas of 200–400 m² g⁻¹), such as Amberlite® XAD-2 or Chromosorb 102®. The latter group are commonly used for the collection of large-molecular-weight, semivolatile organic compounds, including pesticides and polyaromatic hydrocarbons, whereas the former are used for VOCs. These polymers are compatible with most solvent systems. Benzene, cyclohexane, hexane, acetonitrile, methylene chloride, methanol, diethyl ether, and carbon disulfide have all been used, either alone or in combination, depending on the analytes being sampled. These sorbents are hydrophobic so that sampling, storage, or recovery of organic compounds are not affected by ambient water vapor.

The polymer Tenax® has also been used for sampling certain compounds such as dinitrotoluene and trinitrotoluene (TNT) with subsequent solvent desorption, although it is more normally used with thermal desorption.

4.3.2.4 Molecular Sieves  Molecular sieves are sorbents tailored to have uniform pore dimensions. The name is usually referred to the silicate minerals known as zeolites, and carbons made from the carbonization of polymer precursors. In general use, very small pores in the low-nanometer range are implied. The surface area of these ultramicroporous materials is very high, and retention is enhanced by three-dimensional interactions with the walls of the pores and with nearby molecules. Thus small, highly volatile molecules can be retained, but molecules larger than the pore dimensions will not enter the sorbent (hence the sieve effect). The main disadvantage of these sorbents is that they adsorb water molecules, which also fit into the pores. Although charcoal is technically hydrophobic, the adsorption of even a few water molecules causes further molecules to bind to them by hydrogen bonding. Carbon molecular sieves are found in several OSHA methods for methylene chloride, acetone, 2-butanone and vinyl chloride.

4.3.3 Sorbents Used with Thermal Desorption  Graphitized carbons and carbon molecular sieves may be used with thermal desorption, either alone or in combinations. Porous polymer sorbents (e.g. Tenax®, Porapak Q® and Chromosorb 106®) are also used alone, or, in the case of Tenax®, which has a high thermal stability, in combination with carbon sorbents.

4.3.3.1 Polymeric Sorbents  The same polymers mentioned under solvent desorption are used in thermal desorption procedures. As thermal desorption has been focused traditionally on collecting samples from relatively clean environments (indoor and ambient air quality investigations), there has been much concern over blank levels
in the sorbent and how low blank levels can be maintained during storage and transportation. Tenax® has been shown to have the lowest blank levels if conditioned properly, and stored appropriately. Other issues of sampling low concentrations include potential interference from artifact formation. Tenax® has been shown to produce oxygenated aromatics such as acetophenone, benzophenone, benzaldehyde, and phenol through reaction with ambient ozone. Nevertheless, Tenax® is one of the most popular sorbents for sampling atmospheres of relatively low concentration (low ppm to ppb total volatile organic compounds (tVOC)).

Workplace atmospheres typically contain higher concentrations (1–1000 ppm). Background becomes less of a problem when sampling these concentrations but capacity more so. Tenax® has a very low surface area and small capacity, and may be overwhelmed by high concentrations. Unfortunately, as thermal desorption tubes are often used without any form of back-up, such breakthrough may go unnoticed. Chromosorb 106® has much higher capacity and is generally regarded as the best all-round sorbent for occupational hygiene investigations.\(^{63}\)

An alternative solution to the problem of capacity is to use tubes containing multiple sorbent beds. The sorbent with the least capacity for very volatile compounds is the first sorbent through which the air passes. Although the volatile compounds will pass through this bed, less-volatile compounds will be adsorbed, and on a sorbent from which they can be released easily. Sorbents are arranged in order of increasing strength of adsorption so that the final bed adsorbs the most volatile compounds. Desorption must take place in the opposite direction for best results. Typically two or three beds are used. The sorbents used must be thermally compatible with each other. In practice, Tenax® or Tenax® GR (a composite of Tenax® and graphitized carbon) are the only polymers with sufficient thermal stability to be placed alongside carbonaceous sorbents.

The use of multibed tubes is relatively new, and issues of collection efficiency and sample storage stability still require careful evaluation.

4.3.3.2 Graphitized Carbons

Graphitized carbons are granular forms of amorphous graphitized carbon black. Several are available with different surface areas, such as Carbotrap (surface area around 100 m\(^2\) g\(^{-1}\)) or Carbotrap C (surface area around 10 m\(^2\) g\(^{-1}\)). They can be conditioned to have low blank levels, and they are compatible with the highest temperatures normally employed in desorption. Their main drawback is that they are friable, and dust caused by poor handling can increase the pressure-drop across the tube, or escape to block capillary lines. In addition, catalytic reactions have been observed with some reactive compounds such as terpenes. Because of their thermal compatibility with each other and with carbon molecular sieve adsorbents, they are frequently used in multibed tubes such as that designed for the semiquantitative screening method 2549 published by the NIOSH\(^5\) or those developed for use by the USEPA.\(^{64}\)

4.3.3.3 Molecular Sieves

Carbon molecular sieves are often used as the final stage of two- or three-stage sorbent tubes to collect the most volatile components. The water that they also collect requires management. One method is to dry the sorbent tube by the passage at ambient temperature of around 300 mL of dry carrier gas prior to desorption. This has the benefit of removing water without disturbing the collected organic vapors.\(^{65}\)

4.4 Coated Sorbents and Filters

Many highly reactive compounds are unsuitable for sampling directly onto sorbents, either because they are unstable or cannot be recovered efficiently. In addition, some compounds may be analyzed more easily, or with greater sensitivity, by derivatizing them first, which can sometimes be achieved during the sampling stage. Typical common examples are the collection of ethylene oxide as bromoethanol with hydrobromic acid-coated charcoal tubes, and the collection of aldehydes as their derivatives with hydroxymethyl piperidine or 2,4-dinitrophenylhydrazine. Reaction rates may be slow so that lower sampling rates may be required to provide greater contact time between the air being sampled and the sorbent. The reaction may also require specific pH or humidity levels for completion. Coated sorbents and filters have become very popular in recent years as a replacement for sampling with liquid absorbers which have problems with breakage, spillage, or liquid evaporation.

4.4.1 Coated Sorbents

The first sorbent available with a coating was silica gel coated with an inorganic acid for more efficient collection of organic amines and ammonia. Others are given in Table 2. The most commonly encountered are those used for formaldehyde. Charcoal may be coated to restrict reaction at active sites (see section 4.3.2.1).

4.4.2 Coated Filters

When reaction rates are sufficiently fast, the depth of a glass-fiber filter whose fibers are coated with a thin layer of reagent is adequate for efficient sample collection. In a standard closed-face three-piece cassette a second filter may be incorporated to detect breakthrough. If it is desired to use the cassette open face, either a second

ring-piece may be added for the extra filter, or two cassettes can be used in series. Although the range of available coated filters is quite large, the most popular methods are those for hydrogen fluoride, glutaraldehyde, aromatic amines, and isocyanates. Coated filters are able to collect particulates less than 10 µm in diameter, in addition to vapors, so are useful when the contaminant may be present in a mixed aerosol/vapor phase (e.g. isocyanates in spray-painting). Commonly used coated filters are listed in Table 2.

5 DIFFUSIVE SAMPLERS

A diffusive sampler is a device that is capable of taking samples of gas or vapor pollutants from the atmosphere at a rate controlled by a physical process, such as diffusion through a static air layer or permeation through a membrane, but does not involve the active movement of the air through the sampler. A number of publications are available which review the use of diffusive samplers for workplace air sampling.66–72 It should be noted that in the USA, the adjective “passive” is sometimes used in describing these samplers and should be regarded as synonymous with “diffusive”.

This type of diffusive sampler should not be confused with the annular or aerosol denuders, which not only rely on diffusion to collect the gas or vapors but also upon the air in question being simultaneously drawn through the annular inlet into the sampler. Aerosol particles have diffusion coefficients too low to be collected on the annular inlet and are trapped on a back-up filter.

5.1 Operating Principles

The mass of the analyte which can diffuse to a suitable sorbent within a certain time is determined by Equation (1) which is derived from Fick’s first law of diffusion:

\[ m_s = \frac{AD(r_1 - r_2)t}{l} \]  

where \( A \) is the cross-sectional area of diffusion path (cm²), \( D \) is the coefficient of diffusion (cm² s⁻¹), \( l \) is the length of diffusion path (cm), \( m_s \) is the mass of analyte sorbed by diffusion (ng), \( t \) is the sampling time (s), \( r_1 \) is the actual mass concentration at the beginning of the diffusion layer \( (l = 0) \) (mg m⁻³), and \( r_2 \) is the actual mass concentration at the end of the diffusion layer (mg m⁻³).

Ideally \( r_1 \) is equal to the concentration of the given analyte in the air outside the diffusive sampler \( (\rho) \), and \( r_2 \) equals zero (zero-sink condition). In that case the magnitude of the diffusive uptake rate, \( A \times D/l \), is dependent only on the diffusion coefficient of the given analyte and on the geometry of the diffusive sampler used.

For some combinations of sampler and contaminant there are factors that can give rise to nonideal behaviour, so that (Equation 2)

\[ m_s = \frac{AD\rho t k}{l} \]  

where \( k \) is the correction factor for nonideal behavior and \( \rho \) is the actual mass concentration of analyte in air (mg m⁻³).
5.1.1 Dimensions of Diffusive Uptake Rate

For a given concentration \( p \) in milligrams per cubic metre of gas or vapor, the diffusive uptake rate is given by Equation (3),

\[
U = \frac{m_s}{pt'}
\]

where \( U \) is the sampling rate (cm\(^3\) min\(^{-1}\)) and \( t' \) is the sampling time (min).

Although the uptake rate \( U \) has dimensions of volume per unit time, this does not indicate a real volumetric flow of air containing the contaminant.

Diffusive uptake rates are sometimes quoted in units of ng ppm\(^{-1} \) min\(^{-1}\). These are practical units, as most environmental analysts use ppm for concentrations of gases and vapors. The dependency of uptake rates on temperature and pressure is explained later. Thus for a given concentration (ppm) of gas or vapor, the sampling rate is given by Equation (4),

\[
U' = \frac{m_s}{\phi t'}
\]

where \( U' \) is the sampling rate (ng ppm\(^{-1} \) min\(^{-1}\)) and \( \phi \) is the volume concentration of analyte in air (ppm, v/v).

Ideal and practical diffusive uptake rates are related by Equation (5),

\[
U' = \frac{UMT_0 P_1}{MVT_1 P_0}
\]

where \( M \) is the molecular weight of the analyte, MV is the molar volume at normal temperature and pressure (NTP) conditions, \( T_0 \) is the normal temperature (typically 298 K in the USA, 293 K in the UK), \( T_1 \) is the temperature at the sampling site, \( P_0 \) is the normal pressure (typically 101 kPa), \( P_1 \) is the pressure at the sampling site.

Note that this equation does not fully take into account the temperature dependence of the diffusion coefficient (see section 5.2.1).

5.1.2 Bias due to the Selection of a Nonideal Sorbent

The performance of a diffusive sampler depends critically on the selection and use of a sorbent or collection medium which has high sorption efficiency. The residual vapor pressure of the sampled compound at the sorbent surface (\( \rho_2 \)) will then be very small in comparison to the ambient concentration, and the observed uptake rate will be close to its ideal steady-state value, which can usually be calculated from the geometry of the sampler and the diffusion coefficient of the analyte in air.

In the case where a weak sorbent is used, then \( \rho_2 \) in Equation (1) is nonzero and \( m_s / t \) will decrease with the time of sampling. Hence \( U \) in Equation (2) will also decrease with the time of sampling. The magnitude of this effect is dependent on the sorption isotherm of the analyte and sorbent concerned, and may be calculated with the aid of computer models.(73,74)

Another manifestation of the same effect is back-diffusion, sometimes called reverse diffusion. This can happen where, some time after sampling has started, the vapor pressure of the analyte at the sorbent surface, \( \rho_2 \), is greater than the external concentration, \( \rho_1 \), for example if a sampler is first exposed to a high concentration and then to a much lower or even zero concentration. This type of exposure profile can occur in certain applications, and the magnitude of any error introduced will depend on whether the period of high concentration occurs at the beginning, middle, or end of the sampling period. The phenomenon has been discussed in detail by Bartley and colleagues(75–77) and a simple test proposed(78) to give an estimate of the maximum bias to be expected between a pulsed exposure and an exposure to a constant concentration, which latter normally provides the basis for the sampler calibration. The extent of back-diffusion can also be modelled theoretically.(73,79)

It is therefore desirable to choose a sorbent with high sorption capacity and low vapor pressure of the sorbed material or of the reaction product formed by a reactive sorbent.

5.2 Environmental Factors Affecting Sampler Performance

5.2.1 Temperature and Pressure

For an ideal diffusive sampler, the dependence of \( U \) on absolute temperature and pressure is governed by that of the diffusion coefficient of the analyte. The latter dependence is given by Equation (6),

\[
D = f(T^{n+1}, P^{-1})
\]

with \( 0.5 < n < 1.0 \).

Hence, the dependence of \( U \), expressed in units of cm\(^3\) min\(^{-1}\) or equivalent is (Equation 7),

\[
U = f(T^{n+1}, P^{-1})
\]

when \( U' \) is expressed in units of ng ppm\(^{-1} \) min\(^{-1}\) or equivalent by application of Equation (6), then the dependence is given by Equation (8):

\[
U' = f(T^{n})
\]

In the latter case, the dependence will be of the order of 0.2–0.4% K\(^{-1}\). In the case of a nonideal sampler, the temperature dependence of \( U' \) may be compensated by the temperature dependence of the sorption coefficient.
of the analyte.\textsuperscript{(80)} In any case, accurate knowledge of the average temperature and pressure during the sampling period is important for a correct application of Equations (3) and (4).

5.2.2 Humidity

High humidity can affect the sorption capacity of hydrophilic sorbents, such as charcoal and molecular sieve. This will normally reduce the sampling time (at a given concentration) before saturation of the sorbent occurs, when sampling becomes nonlinear because of a significant $p_2$ term in Equation (1). High humidity can also alter the sorption behavior of the exposed inner wall of tube-type samplers or draught screen, particularly if condensation occurs.

5.2.3 Transients

Simple derivations of Fick’s law assume steady-state conditions, but in the practical use of diffusive samplers, the ambient level of pollutants is likely to vary widely. The question then arises as to whether a sampler will give a truly integrated response (ignoring sorbent effects) or will miss short-lived transients before they have had a chance to be trapped by the sorbent. The passage of molecules into the diffusion path, followed by their diffusion back out of the sampler when the external concentration has dropped to zero and before the molecules have reached the sorbent bed has also been termed ‘reverse diffusion’. Although the effects are similar the cause is different from that referred to in the section on nonideal behavior listed above. In that case the cause is related to the strength of the sorbent, in this case to the geometry of the sampler. The problem has been discussed theoretically\textsuperscript{(72, 81–83)} and practically\textsuperscript{(81, 84–85)} and shown not to be a problem, provided the total sampling time is well in excess of (say 10 times) the time constant of the diffusive sampler, i.e. the time a molecule takes to diffuse into the sampler under steady-state conditions. The time constant $\tau$ for most commercial samplers is between about 1 and 10 s and is given by (Equation 9):

$$\tau = \frac{l^2}{D}$$  \hspace{1cm} (9)

5.2.4 Air Velocity

5.2.4.1 Effect of Low and High Wind Speeds

Ambient air face velocity and orientation can affect the performance of a diffusive sampler because they may influence the effective diffusion pathlength.\textsuperscript{(86–89)} The diffusive mass uptake of a sampler (Equation 2) is a function of the length $l$ and the cross-sectional area $A$ of the diffusion gap within the sampler. The nominal diffusion pathlength is defined by the geometry of the sampler and is the distance between the sorbent surface and the external face of the sampler. The cross-sectional area is also defined by the geometry of the sampler and if the cross-section of the diffusion gap is not constant along its length, is defined by the narrowest portion. The effective length, $l$, is not necessarily the same as the nominal length, and may be greater or less, depending on circumstances.

Under conditions of low external wind speeds, the effective diffusion pathlength may be increased.\textsuperscript{(88, 89)} This is because a boundary layer\textsuperscript{(86, 87)} exists between the stagnant air within the sampler and the turbulent air outside and contributes to the effective diffusion pathlength $l$. In reality, there is an area outside the sampler where there is a transition between static air and turbulent air, but this is equivalent to an extra length $(\delta l)$ of static air which must be included in the value of $l$. The value of $\delta l$ depends on the external geometry of the sampler, being roughly proportional to the linear cross-section of the sampler collection surface, where this surface is flat. It also decreases with increasing air velocity. Its significance depends on the value of the nominal pathlength of the diffusive sampler. Thus a sampler with a small cross-section and long internal air gap will be relatively unaffected by air velocity, whereas a short, fat sampler will be significantly affected. This is borne out in practice, as has been demonstrated with samplers of varying length.\textsuperscript{(88, 89)} Low sampling rates are observed at low air velocities, but increase to a plateau value as the boundary layer effect becomes insignificant.

Under conditions of high external wind speeds, the effective diffusion pathlength may be decreased.\textsuperscript{(90–96)} This is because turbulent air disturbs the static air layer within the sampler, which reduces the effective air gap by a factor $\delta l$. The value of $\delta l$ is small, provided the length to diameter ratio of the sampler air gap is greater than 2.5–3.\textsuperscript{(90)} or it can be avoided, or greatly reduced, by incorporating a draught shield, such as a stainless steel screen or plastic membrane.

The overall effect is therefore sinusoidal.

5.2.4.2 Consequence for Different Sampler Geometries

Tube-type samplers are typically unaffected by low air velocities\textsuperscript{(83, 97, 98)} but those without a draught shield may be affected by high speeds. Badge-type samplers generally have a large surface area and small air gap, so that they may be more affected by air velocity than tube designs and typically require a minimum face velocity of between 0.2 and 0.5 m s$^{-1}$.\textsuperscript{\textsuperscript{(67, 99–101)}} Some badges with an inadequate draught shield are also affected at high air velocities.\textsuperscript{(98, 99, 102)}

Radial diffusive samplers\textsuperscript{(103)} require a minimum face velocity of about 0.25 m s$^{-1}$.\textsuperscript{\textsuperscript{1}}
5.2.5 Sources of Methods and Uptake Rates

In general, the regulatory authorities have been reluctant to accept diffusive monitoring methods, except in some countries, for example the UK and the Netherlands. Extensive lists of recommended sampling rates for solvent desorption methods are given in The Diffusive Monitor and the UK HSE Method MDHS 88. Extensive lists of recommended sampling rates for thermal desorption methods are given in The Diffusive Monitor and the UK HSE Method MDHS 80. The situation with regard to regulatory acceptance is changing slowly. In the USA, the OSHA Technical Center has begun a program of sampler validation and has published the first of a series of methods (Method 111, toluene) featuring diffusive samplers.

6 SAMPLING DEVICES WITH DIRECT READOUT

There are two types of sampling devices which provide immediate or on-site read-out covered in this section, and a third that combines elements of the other two. In the first type, colorimetric diffusive samplers, uptake is by diffusion (see section 5) and a progressive reaction of an air contaminant with a chemical coating on the substrate develops a color that may be read by eye or by a portable instrument. In the second type, detector tubes, air is pulled through a chemically coated sorbent in a graduated tube. The concentration of a contaminant is related to the length of stain caused by the reaction between the contaminant and the sorbent coating. These tubes are typically for short-term almost instantaneous measurements, but diffusive types are also available that can be used for long-term measurements. This type has elements of both of the other types. All of these devices are especially suitable for simple, reactive contaminants that have few interferences. Examples of such chemicals include phosgene, ammonia, chlorine, and formaldehyde. The detector tube devices can be useful for more complex chemicals or mixtures by incorporation of multiple layers, including sections to humidify or dry the sample, activate the chemical, or to remove interferences (precleanse layer). Detector tubes are very useful for identifying hazardous atmospheres but are less often used for exposure monitoring because of their short sampling periods and the high cost of multiple samples to cover a longer period. Diffusive devices are popular with large industries which have performed in-house validations and are satisfied with the sampler performance, but only very few have been tested by government agencies. A very useful reference work on these devices has been published. A manual of proper practice for detector tubes also is available. The theoretical aspects of sampling with diffusive samplers (section 5) extends also to those samplers that develop a color. Measurement of the developed color can be done qualitatively, by comparison with colored standards, or quantitatively using a spectrophotometer, normally in reflectance mode. The propagation of light within an opaque medium is a very complex process that can be solved mathematically if certain assumptions are made, and the resulting calibration is inherently nonlinear. However, there is usually a narrow range of concentration over which the calibration can be considered linear, and this can be extended by appropriate mathematical transformation of the raw data. Relatively inexpensive devices are available for this purpose. Where the color develops as a length of stain, as is the case with detector tubes, the situation is somewhat different, and is described below.

6.1 Operation of Detector Tubes

The two ends of the tube are broken by a device provided by the manufacturer which ensures an opening of sufficient width not to limit flow into the tube. The tube is then placed in the manufacturer’s holder which is fitted with a squeeze bellows or piston pump for short-term grab samples, or connected to a pump for long-term samples. Diffusive-type detector tubes are placed in their own special holder. The correct amount of air is drawn through the short-term samplers by applying the appropriate number of strokes of the bellows or piston pump, each stroke being typically 100 mL. Care must be taken to allow adequate time for the vacuum to reach equilibrium with the ambient pressure, and also to make sure all connections are leak-tight. Manufacturer’s instructions should be followed exactly; most manufacturers and applicable standards advise against substituting pumps from different manufacturers, as the pump and tube are certified as a unit. The number of strokes varies from one to as many as 100, and the number usually can be increased to increase sensitivity. Some pumps are equipped with stroke counters to ensure the correct number is taken. One hundred strokes usually require a considerable time to accomplish and such samples are time-weighted averages. Short-term detector tubes can be used to determine time-weighted average concentrations for up to 8 h or more, provided a sufficient number of samples is taken, but this will usually not prove to be cost-effective. Long-term tubes are used in the same way as sorbent tubes; diffusive versions have a defined diffusion path. In all cases, the length of color change is read against a calibration marked on the outside of the tube. The type of color change depends on the reaction chemistry, and may be more or less easy to determine by eye. Detector tubes are carefully made to provide...
sharp reaction fronts where possible, but sometimes the boundary is diffuse and difficult to identify. Reading the concentration value is the single largest source of error associated with these devices, and the accuracy may not reach the requirements normally required for monitoring for compliance purposes. Recently, electronic devices have been made available to reduce the variation associated with reading tubes by eye.

6.2 Chemical Reactions used in Detector Tubes

Several useful chemical reactions are widely employed in detector tubes. These reactions include reductions (e.g. of chromate or iodine pentoxide), color change of pH indicators, and reactions to form dyes (e.g. with o-tolidine or tetraphenylbenzidine). However, these reactions are often not specific to a single contaminant, and cross-sensitivity must be taken into account when using these devices. Sometimes the same reaction may be involved in two different tubes, only the calibration being different. The reacting chemicals are impregnated on inert supporting material, such as silica gel, alumina, ground glass, pumice, or resin. Precleanse layers may be used to remove water vapor or other interferences (e.g. hydrogen chloride when measuring hydrogen cyanide). In addition, there may be reactive layers that produce a product that is measured by the color reaction (e.g. liberating halogen from a halogenated hydrocarbon). Because many of these chemicals are very reactive, long-term storage may not be possible. A shelf-life of at least 2 years is desirable; in general, shelf-life may be improved by refrigerated storage.

6.3 Theory of Operation

In the general case where the sampling period is relatively short and the flow-rate is relatively high, complete equilibrium is not reached between the contaminant gas or vapor and the chemical reactants, and the length of stain is determined by the kinetic rate of reaction. In theory,(112) the stain length is proportional to the logarithm of the product of gas concentration and sample volume (Equation 10):

\[
\frac{L}{H} = \ln(CV) + \ln \frac{K}{H}
\]

where \( L \) is the stain length (cm), \( K \) is a constant that varies with type of tube and analyte gas or vapor (cm\(^{-2}\)), and \( H \) is the mass transfer proportionality factor (cm). Thus a plot of stain length \( L \) against the logarithm of the product \( CV \) yields a straight line of slope \( H \).

If the reaction rate is sufficiently fast that equilibrium can be attained, the general Equation (10) reduces to

\[
L = KC'V
\]

Equation (11) generally holds true for long-term detector tubes, where the concentration is calculated from the volume sampled. For stain-length passive (diffusive) dosimeters, Fick’s law (Equation 1) is combined with Equation (11) to give Equation (12):

\[
rL + L^2 = KDAC't
\]

where \( r \) is the diffusive pathlength (cm).

6.4 Certification of Detector Tubes

A performance evaluation program of detector tubes was initiated by the NIOSH in the late 1960s and early 1970s. Many tubes were found at that time to have accuracies in the range ±25% to ±35%. A formal certification program, with testing by the NIOSH in Morgantown, WV, was put in place,(113,114) but was dropped 10 years later for lack of funding. In 1986, the Safety Equipment Institute (SEI) announced a voluntary program for third-party certification,(115) which continues today. However, in a recent air sampling instruments workshop,(116) the program was criticized mainly on the grounds of having too narrow a scope of testing. Detector tubes are the subject of many national and international standards; some examples are given from the USA, Japan, and the UK.(117–119)

7 CALCULATIONS

Prior to calculating concentration from a sampling result, it is important to keep in mind the use to which the result will be put. The results of most sampling exercises are to be compared to a regulated or recommended limit value. The ultimate source of most of the limit values in use around the world are the TLV® of the American Conference of Governmental Industrial Hygienists (ACGIH). These values are given in units of parts per million by volume (ppm) at NTP (or 25°C, one atmosphere, in the USA). The results obtained from pumped sampling exercises are in units of mass per unit volume (e.g. mg m\(^{-3}\)), which can be compared to the limit value by using the molar volume of the chemical at NTP in the calculation. The handling of results from diffusive sampling exercises is more complex, as the diffusion coefficient varies with pressure and temperature, whereas, as explained above, the volume of a pump does not. In order to compare a result to the ACGIH TLV® it is necessary either to correct the uptake rate (which is normally given for NTP) for pressure and temperature and use the molar volume at NTP, or to use the molar volume at the sampling site conditions of pressure and temperature. This procedure is to be used, for example, for comparing results to OSHA permissible exposure limits (PELs). Other
government regulations may vary. These corrections are not insignificant. At an altitude of 6000 ft (approximately 2000 m) the correction is around 17%. Outdoors during freezing weather the correction is around 12%.

The collected sample is analyzed, either directly if it is a gas-phase or impinger sample, or after desorption if it is collected on a solid sorbent, using appropriate gas or liquid standard solutions to calibrate the analytical instrument. The mass concentration of the analyte in the air sample is then calculated using the following equations.

### 7.1 Absorber

This is given by Equation (13):

$$ C = \frac{m - m_{\text{blank}}}{E_d V} $$  \hspace{1cm} (13)

where $C$ is the mass concentration of analyte in the air (mg m$^{-3}$), $m$ is the mass of analyte in the sample (µg), $E_d$ is the sampling efficiency, $m_{\text{blank}}$ is the mass of analyte in blank (µg), and $V$ is the volume of air sample (litres).

### 7.2 Sorbent Tube

This is given by Equation (14):

$$ C = \frac{m_1 + m_2 - m_{\text{blank}}}{E_d V} $$  \hspace{1cm} (14)

where $m_1$ is the mass of analyte in first tube section (µg), $m_2$ is the mass of analyte in back-up tube section (if used) (µg), and $E_d$ is the desorption efficiency corresponding to $m_1$.

### 7.3 Volume Fraction

If it is desired to obtain a result in ppm at NTP that can be compared directly to an ACGIH TLV® or OSHA PEL, Equation (15) is used:

$$ C^* = C \frac{MV}{M} $$  \hspace{1cm} (15)

### 7.4 Diffusive Sampler

The method of calculation of atmospheric concentrations is essentially the same as for pumped samplers, i.e. the collected sample is analyzed and the total weight of analyte on the sampler is determined (Equation 16):

$$ C = \frac{m_1 + m_2 - m_{\text{blank}}}{E_d V} $$  \hspace{1cm} (16)

Note that $m_2$ is relevant only to samplers with a back-up section, and an additional multiplication factor may be needed to account for differing diffusion pathlengths to primary and back-up sections.

The total sample volume $V$ is calculated from the product of the effective sampling rate (L min$^{-1}$) and the time of exposure (min). The sampling rate should be corrected for the ambient temperature and pressure as stated above. This calculation gives $C^*$ in ppm at NTP:

$$ C^* = \frac{C \times MV}{M(T_1/T_0)^{1.5}(P_0/P_1)} $$  \hspace{1cm} (17)

Equation (17) provides results that can be directly compared to an ACGIH TLV® or OSHA PEL.

## 8 STANDARDS

### 8.1 European Standards

The task of developing appropriate standards for workplace air quality measurements within the European Community has been carried forward by working groups (WGs) of CEN (European Committee for Standardization) Technical Committee TC 137. This committee took the view that air quality assessment standards should take the form of performance requirements rather than prescribed methods. This approach has the advantage of allowing any method to be used which meets these requirements without stifling innovation and development. The actual writing of standard measurement procedures was taken to be the role of ISO (International Organization for Standardization) or member state regulatory bodies, such as HSE (for example the MDHS series).

The approach taken by WG2 has been to develop a hierarchy of standards with a general performance requirements document at the top and a series of specialized standards under this umbrella.

#### 8.1.1 Umbrella Standard

The umbrella standard(120) provides, among other things, definitions and minimum requirements for unambiguity (the uniqueness of the result), selectivity (which depends on whether detailed knowledge of the air composition is known in advance) and overall uncertainty (a combination of precision and bias).

#### 8.1.2 Second-tier Standards

These standards contain specific (minimum) performance requirements for measuring devices, together with the appropriate test methods. So far, the standards for diffusive samplers, pumped sorbent tubes, detector tubes, and low-volume sampling pumps have been published. Standards are being prepared for high-volume pumps, sampling and analysis of metal species (or, more generally, of chemical agents in airborne particles), samplers for mixed aerosols and vapors and, jointly with a
CENELEC (European Electrotechnical Committee for Standardization) WG, for direct-reading electrical apparatus. Guidance is also being prepared for chemically impregnated systems and for the selection of procedures and devices.

8.2 US Standards

8.2.1 Government Standards

Agency standards include those issued by the NIOSH, OSHA, and the USEPA. The NIOSH has published a manual on sampling strategy\(^{125}\) and also guidance for method development and evaluation.\(^{126}\) In addition, the introduction to the Manual of Analytical Methods\(^{53}\) contains much valuable information. NIOSH methods are considered to be guidance, rather than regulations, and may be modified as necessary, provided suitable evidence of equivalent performance has been documented. OSHA inspectors and analytical laboratories are required to use OSHA methods where possible, and NIOSH or other methods where these do not exist. There is no obligation on private parties to use OSHA or NIOSH methods, and the existence of data gathered using these methods will not necessarily prevent an OSHA assessment. The USEPA has regulations concerning the assessment of exposures to pesticides and has published guidelines for exposure monitoring. The USEPA does not regulate indoor air quality and the Compendium methods are for guidance only.\(^{127}\)

8.2.2 Voluntary Consensus Standards

Public Law 104-113 includes a requirement for federal government agencies to make use of voluntary consensus standards where possible, rather than duplicating the standard-setting process themselves. The two major organizations involved in standardization are the ASTM (see section 2) and the American National Standards Institute (ANSI). The ASTM has published many standards on workplace air measurement through its committee D22, which are published in the annual book of standards.\(^{128}\) A selection of different standard guides, practices and test methods is given in Table 3. The ANSI has many standards on worker protection, such as those concerning respirators, but has relatively few\(^{111,129}\) that deal with air sampling or analysis. This situation may change as the AIHA has become a secretariat to the ANSI. The AIHA is in the process of collating and publishing a compendium of standards and good practices in occupational hygiene, which will include a chapter on sampling and analysis.

8.3 Standards Issued by International Organization for Standardization

Several ISO standards have been developed for monitoring VOCs. These include ISO 8762: 1988 (vinyl chloride by charcoal tube),\(^{130}\) ISO 9486: 1991 (chlorinated hydrocarbons by charcoal tube),\(^{131}\) and ISO 9487:
1991 (aromatic hydrocarbons by charcoal tube). More recently, a generic method for VOCs using thermal desorption has been developed by TC146/SC6/WG5 as draft ISO/DIS 16017. This is in two parts, pumped sampling and diffusive sampling and is applicable to workplace, indoor and ambient air. An equivalent solvent desorption method is being developed by SC2/WG4 as ISO/DIS 16200, but this is applicable only to workplace air.

Standards are being developed in TC146/SC6/WG3 for the measurement of VOCs in emissions from building materials and for formaldehyde in indoor air (both pumped and diffusive).

Standards for the measurement of inorganic gases in ambient air are also available. These include ISO 7996: 1985 (nitrogen dioxide) and ISO 6767: 1990 (sulfur dioxide by the p-rosaniline method). There are also two detector tube methods for the measurement of inorganic gases in workplace atmospheres: ISO 8760: 1982 (carbon monoxide) and ISO 8761: 1982 (nitrogen dioxide).

9 QUALITY SYSTEMS AND QUALITY CONTROL

The primary control of method quality is validation. Methods are validated by government agencies, academic researchers, corporate occupational hygiene departments, independent research institutes, or equipment manufacturers. Protocols for performing method validation are published, and fall into two types – laboratory and field. Laboratory-based protocols allow reference to atmospheres of traceable standard concentration, whereas field protocols involve comparison to a previously validated reference method. Validation studies are limited to a defined set of conditions and use of the sampling method beyond the tested range is appropriate only if the results are treated with caution.

Sorbents that are treated with reactive chemicals may show considerable batch-to-batch variation. These variations may be magnified where the measurement is based on some property of the chemical, such as a color reaction. In length-of-stain color detector tubes it is very important to check each batch for potential biases caused by variations in sorbent mesh-size, packing, and coating, and also in the measurement marks applied to the outside of the tube. As mentioned above, the US SEI oversees a testing program for detector tube certification based on a program originally designed by the NIOSH.

Quality systems are available for canister sampling. It is possible to fill canisters with inert gas and check the background for memory effects from prior samples. It is possible to add certified quantities of the analyte(s) of interest to the canister after sampling (matrix addition) or to add an internal standard that will not interfere with the analysis, and it is possible to obtain canisters containing certified quantities of analyte(s) as external standards. It is normally possible to analyze more than one aliquot of the same sample. If a secondary trap is used in the analysis, it may be possible for standards to be added to the trap to determine the recovery efficiency. Round-robin programs are not available for the occupational use of canisters but may be available for environmental levels.

Several quality assurance schemes have been developed that apply to the commonest methods of workplace air sampling: sorbent tubes and diffusive samplers for VOCs, and filters for metal particulates, silica and fibers. The Sampling and Laboratory Analysis Committee of the AIHA has published a Laboratory Quality Assurance Manual in both English and Spanish. It recommends the use of reagent and matrix blanks, calibration standards, internal standards, external reference materials, matrix spike additions, and replicate analyses where appropriate. It also discusses how the results from these measurements can be used in an on-going control program. Round-robin and proficiency schemes are also important. One such is the Proficiency Analytical Testing (PAT) Program of the Analytical Accreditation Committees of the AIHA. Another is the UK HSE Workplace Analysis Scheme for Proficiency (WASP). Details of these programs may be obtained from The Laboratory Accreditation Co-ordinator, AIHA, 2700 Prosperity Ave., Suite 250, Fairfax, Virginia 22031, and the WASP Co-ordinator, Health and Safety Laboratory, Broad Lane, Sheffield, S3 7HQ, United Kingdom.

The WASP scheme also includes test samples appropriate to the thermal desorption technique, at both occupational and ambient concentration levels. Certified reference materials are available from the EC (European Commission) BCR (Community Bureau of Reference) for aromatic hydrocarbons (CRM 112) and chlorinated hydrocarbons (CRM 555).

An occupational sampling program is of little value unless proper care has been taken in the selection of sampling and analytical method, the timing and placement of sampling, and the interpretation of results. Many countries have organizations for the training and certification of hygiene professionals.

Scattering and Absorption of γ-Rays and Thermalization and Disappearance of Neutrons

M. Borsaru
CSIRO-Exploration and Mining, Kenmore, Queensland, Australia

1 Introduction
The interactions of γ-radiation and neutrons with matter form the basis of a large number of nuclear techniques developed for chemical analysis or used to infer properties of interest in logging. Nuclear techniques have the ability to measure properties of materials without contact and, because of the high penetration of both γ-radiation and neutrons, enable measurements to be made through walls. In borehole-logging applications, these two types of penetrating radiation can traverse the pressure housing of the logging tools and the formation and return a signal carrying information about the surrounding formation and the rock matrix.

This article presents the principles of the interaction of γ-rays and neutrons with matter and outlines geological/mineral applications. The emphasis is on nuclear borehole logging. Because of the deep penetration of neutrons and γ-rays, nuclear techniques are well suited to borehole-logging applications. The volume of matter investigated by nuclear radiation is much larger than the core analyzed from a cored borehole, so a more representative sample is analyzed.

Well logging grew from the need of the petroleum industry to evaluate hydrocarbon formations. Today, borehole logging is a mature technology, and nuclear logging is well established in the oil, gas, uranium and coal industries. It is also making inroads in the mineral industry. It is now very difficult to imagine these industries without logging.

Nuclear logging, employing in situ γ-ray spectroscopy, can measure the chemical composition of the earth formation, thereby providing an indication of the dominant mineralogy. This is vital information in oil well logging. In situ γ-ray spectroscopy replaces the time-consuming chemical analysis of the core in a laboratory. Bulk density, which is another important property of an earth formation, is measured by γ-ray scattering. Some minerals contain the natural radioactive elements potassium, thorium and uranium. The detection of their γ-radiation indicates the presence of these elements, and quantitative measurements can be made of their concentration.

Nuclear applications are an integral part of today’s measurement technologies, contributing to increased
efficiency and large financial savings in industry. Although a mature technology, new applications are still being found.

2 SCATTERING CROSS-SECTION

For the study of neutron and γ-ray scattering it is convenient to introduce the scattering cross-section. For a very thin target bombarded with neutrons or γ-rays, the number of scattered particles is very small compared with the number of particles in the beam, as shown in Equation (1):

\[-\frac{dN}{N} = A \, dx = n \sigma \, dx\]  \hspace{1cm} (1)

where \(-dN\) is the number of scattered particles, \(N\) is the number of incoming particles, \(dx\) is the thickness of the target and \(A\) is a proportionality constant dependent on the number of nuclei per unit volume \(n\) and the nature of the nuclei, represented by \(\sigma\), the scattering cross-section. For a thicker target, the number of particles passing through undeflected, \(N\), is obtained by integrating Equation (1), illustrated in Equation (2):

\[N = N_0 \, e^{-\mu x}\]  \hspace{1cm} (2)

where \(N_0\) is the total number of particles in the beam which hit the target. The total number of particles scattered from the beam is shown in Equation (3):

\[N_{sc} = N_0 (1 - e^{-\mu x})\]  \hspace{1cm} (3)

When the target contains several isotopes of different cross-sections, \(n \sigma\) is replaced by \(n_1 \sigma_1 + n_2 \sigma_2 + n_3 \sigma_3 + \cdots\)

3 SCATTERING AND ABSORPTION OF γ-RADIATION

γ-Rays are electromagnetic radiation, as are X-rays, light, radio waves, etc. For γ-rays or neutrons, the processes by which they interact with matter are such that a single event will remove the γ-ray or neutron from the beam. According to Equation (2), the intensity of the beam hitting a target will decrease exponentially, as illustrated in Equation (4):

\[N = N_0 \, e^{-\mu x}\]  \hspace{1cm} (4)

where the constant \(\mu\) is called the absorption coefficient and has dimension (length)^{-1}. It is also common to measure absorber thickness in g cm^{-2} and write Equation (4) as Equation (5):

\[N = N_0 \, e^{-\mu \xi}\]  \hspace{1cm} (5)

where \(\xi = \rho x\) is the mass per unit area and where the mass absorption coefficient \(\mu_m\) is, as illustrated in Equation (6):

\[\mu_m = \frac{\mu}{\rho} = \frac{n \sigma}{\rho} = \frac{N_A \sigma}{M_A}\]  \hspace{1cm} (6)

\(N_A\) is Avogadro’s number, \(M_A\) is the atomic weight of the element in the absorber and \(\rho\) is the density. If more elements are present in the absorber, then Equation (7) applies:

\[\mu_m = N_A \sum \frac{\alpha_i \sigma_i}{M_{Ai}}\]  \hspace{1cm} (7)

where \(\alpha_i\) is the abundance ratio of the \(i\)th element.

The interaction of γ-radiation with matter in the energy range from 50 keV to 50 MeV is dominated by three processes: (1) photoelectric effect, (2) Compton effect and (3) pair production.

3.1 The Three Principal Processes

3.1.1 The Photoelectric Effect

In the photoelectric effect, predominant at low energies, the γ-ray (photon) gives all its energy to a bound electron. The electron, to overcome its binding energy in the atom, uses part of the energy and the rest is taken as kinetic energy. The energy of the emitted electron is therefore \(E_e = E_{\gamma} - E_b\), where \(E_{\gamma}\) is the γ-ray energy and \(E_b\) is the binding energy of the electron in the atom, usually the k-shell energy. The probability of photon interacting with an electron in a given orbit is higher when the energy of the photon is equal to the binding energy and decreases with increasing energy. The electron gives up its energy to other atoms and eventually falls back into an orbit. The X-rays emitted following the capture of the electrons into orbits interact with the matter again and again until all the energy is absorbed either at very low-energy orbital levels or other mechanisms which are outside the scope of this article.

The cross-section of the photoelectric absorption per atom is a function of photon energy, \(E\), illustrated in Equation (8), and is approximated\(^{[1]}\) as being proportional to:

\[\sigma(E) \approx \frac{Z^{4.5}}{E^{2.5}}, \hspace{0.5cm} 2.5 \leq n \leq 3.5\]  \hspace{1cm} (8)

The mass absorption coefficient for the photoelectric effect is shown in Equation (9):

\[\mu_{mph} = \rho N_A \sum \frac{\alpha_i \sigma_i(E)}{M_{Ai}}\]  \hspace{1cm} (9)

The contribution of the photoelectric effect at low energies is significant for heavy elements because of...
their high atomic number. For lighter elements, the contribution of the photoelectric effect is reduced as a result of the linear relationship between its cross-section and $Z^4$.

### 3.1.2 The Compton Effect

The Compton effect predominates around 1 MeV. It implies scattering of photons by the atomic electrons. The photon is deflected from its trajectory with or without loss of energy, as shown schematically in Figure 1 ($\nu$ is the frequency of the photon of wavelength $\lambda$, where $v = 1/\lambda$). This happens at photon energies much larger than the electron binding energies so that, theoretically, the electrons can be considered free. Expressions for the energy $h\nu'$ of the scattered photon, the energy $T$ of the scattered electron and the relationship between the angles of scattering shown in Figure 1 are given in Appendix 1. The cross-section for the Compton scattering was calculated by Klein and Nishina.\(^2\) It is well described by Davisson\(^3\) and many other books of nuclear physics or quantum mechanics.

### 3.1.3 The Pair Production Effect

In the pair production effect, a photon disappears with the creation of an electron/positron pair. The total kinetic energy of the resultant particles is equal to the photon energy minus the mass energy of the electron/positron pair created by the interaction (1.02 MeV) and therefore the pair production effect cannot take place below 1.02 MeV. Figure 2 shows schematically the pair production effect. The pair production takes place in the field of a nucleus or electron with no change of the state of the nucleus or its electrons. The nucleus must be present to absorb some of the momentum of the photon. Pair production cannot take place in the absence of the nucleus or electron because the conservation of energy and conservation of momentum cannot be simultaneously observed.

### 3.2 Other Interactions of $\gamma$-Rays With Matter

The photoelectric, Compton and pair production effects are the major interactions of $\gamma$-rays with matter and contribute most of the total $\gamma$-ray attenuation coefficient in the energy region being considered. However, they are not the only interactions. Other interactions of interest are resonance scattering of $\gamma$-rays and photonuclear reactions, also called $\gamma$-activation. There are other interactions (Thomson, Delbrück, Rayleigh) which occur at low energies. They are treated in more specialized books and are outside the scope of this general article.

#### 3.2.1 Resonance Scattering

$\gamma$-Ray resonance scattering is an elastic process that takes place via an excited state of a stable nucleus. If the energy of the $\gamma$-ray corresponds exactly to the energy level of the stable nucleus, the nucleus can absorb this $\gamma$-ray and become an unstable excited nuclear state. The nucleus will regain its stable state by emitting a $\gamma$-ray that is theoretically of the same energy as the one absorbed. In practice, the $\gamma$-ray emitted by the excited nucleus at rest has less energy than the photon that excited the nucleus, $E_\gamma$, because of the recoil energy taken by the nucleus. If $M$ is the mass of the emitting atom, conservation of energy and momentum leads to the expression for the energy of the emitted photon $h\nu$: $h\nu = E_\gamma - (E^2/2Mc^2)$. The same amount of kinetic energy is transferred to the nucleus which is excited by the $\gamma$-ray, so that the total energy displacement is $\Delta E = E^2/Mc^2$. In general, $\Delta E$ is large by comparison with the width of the energy level $\Gamma$ and the system is out of resonance, in other words...
the cross-section for resonance absorption is small. From Heisenberg’s principle, \( \Gamma (eV) = 6.58 \times 10^{-16}/\tau \), where \( \tau \) is the lifetime of the excited state in seconds. This is why it took a long time to prove the existence of \( \gamma \)-ray resonance scattering.

Mössbauer discovered that an atom embedded in a crystal lattice can emit or absorb \( \gamma \)-radiation without loss from the recoil because the momentum is taken up by the crystal as a whole with negligible energy loss. There are a few methods of producing resonance scattering. The change of quantum energies can be achieved by moving the absorber and the radiation source with respect to each other (based on the Doppler effect). Another practical technique to obtain \( \gamma \)-rays of the precisely defined energy for resonance scattering is to choose a radioisotope source that decays via the excited state of the chosen element. For example, if the element chosen for \( \gamma \)-ray scattering is \( ^{60}\text{Ni} \), a \( ^{60}\text{Co} \) source may be used. \( ^{60}\text{Co} \) decays by \( \beta^- \) and \( \gamma \)-ray emission via excited states of \( ^{60}\text{Ni} \). Matching the radioactive source to the chosen element is essential for \( \gamma \)-ray resonance. Resonance scattering does not take place when the \( \gamma \)-ray source is in a solid state because the recoil energy losses during the emission of \( \gamma \)-rays make it deficient in energy by several tens of keV. This deficiency may be overcome by using a gaseous source. \( \gamma \)-Rays from gaseous sources are Doppler broadened so that about 1% of the \( \gamma \)-rays are in resonance.

\( \gamma \)-Ray resonance scattering has found practical applications. Mössbauer spectroscopy is a powerful technique for elemental analysis based on this effect. Copper and nickel are two favorable elements for analysis by \( \gamma \)-ray scattering using vapor sources of \( ^{65}\text{ZnI}_2 \) and \( ^{60}\text{CoBr}_2 \) respectively.

### 3.2.2 Photonuclear Reactions

\( \gamma \)-Rays of high energies can produce nuclear reactions with atomic nuclei. If the incident \( \gamma \)-ray energy exceeds a threshold energy, it is possible to remove particles from stable nuclei. Each element is characterized by a particular threshold energy. The most frequent nuclear reactions induced by high-energy \( \gamma \)-rays in the energy range of interest are \( (\gamma, n) \) processes. The maximum cross-section for light elements is at 20–25 MeV and \( \approx 15\text{MeV} \) with other elements. The photonuclear reaction has found practical applications mostly for the determination of low-atomic-number elements. The technique is selective if the \( (\gamma, n) \) threshold energies are selected appropriately.

The only reactions to have threshold energies less than 2.5 MeV are the \( (\gamma, n) \) reactions for \( ^9\text{Be} \) (threshold \( = 1.67\text{MeV} \)) and \( ^2\text{H} \) (2.22 MeV). The \( (\gamma, n) \) reaction with beryllium has been used in different techniques of analysis for this element. \( ^{124}\text{Sb} \) is a suitable \( \gamma \)-ray source for beryllium analysis. It has a half-life of 60 days and emits \( \gamma \)-rays of 1.69 and 2.09 MeV. The average energy of neutrons from the \( ^{7}\text{Be}(\gamma, n) \) reaction using a \( ^{124}\text{Sb} \) source is approximately 24 keV. The neutrons are moderated in a hydrogenous moderator and detected with thermal neutron detectors such as \( ^{10}\text{BF}_3 \) or \( ^{3}\text{He} \) counters.

### 3.3 Density and Composition Measurements

#### With \( \gamma \)-Rays

The three major interactions of \( \gamma \)-radiation with matter have found wide industrial applications. Here we review the basis of density and composition determination.

The Compton mass attenuation coefficient \( \mu_c \) for photon energies much larger than the electron binding energies can be expressed as (Equation 10):

\[
\mu_c = \left( \frac{\rho N_A Z}{M_A} \right) e_\mu
\]

where \( \rho N_A / M_A \) represents the number of atoms per cubic centimeter, \( Z \) is the number of electrons in the atom and \( e_\mu \) is the Compton scattering cross-section per electron. For a \( \gamma \)-ray of given energy (Equation 11):

\[
\mu_c = \frac{Z}{M_A} \rho
\]

Except for hydrogen, the \( Z/M_A \) ratio for low-\( Z \) elements (which form the Earth’s crust) is very nearly a constant equal to \( \frac{1}{2} \). For hydrogen, \( Z/M_A = 1 \), and this introduces an error when hydrogenous material is present in matter investigated. If the energy of \( \gamma \)-rays is greater than 300 keV, one can neglect the photoelectric effect and assume that the interaction is by the Compton effect. Equation (4) can be used to derive Equation (12):

\[
\log N = \log N_0 - \mu_c x = \log N_0 - \frac{Z}{M_A} \rho x
\]

For a radioactive source of long half-life, \( N_0 \) is constant. By plotting a graph of \( \log N \) vs density (\( \rho \)), one obtains a straight line if the thickness \( x \) of the materials of different densities is constant. The density is extracted from this linear relationship.

#### Concept of Equivalent Atomic Number, \( Z_{eq} \)

In order to facilitate measurement of the chemical composition of a medium by \( \gamma \)-scattering, Czubek\(^{1}\) introduced a quantity called the equivalent atomic number (\( Z_{eq} \)) of the scattering medium in terms of photoelectric and Compton coefficients. We have seen that the Compton and photoelectric absorption coefficients (\( \mu_{ph} \) and \( \mu_{pe} \)) for given \( \gamma \)-ray energies are proportional to \( (Z/M_A)\rho \) and \( (Z^{1/3}/M_A)\rho \) respectively. Therefore, \( \mu_{ph}/\mu_{pe} = \text{const} \cdot Z^{3/5} \). One can

---

show that, for a mixture of elements (Equation 13):

\[ Z_{eq} = Z = \sum_i W_i Z_i^{1.5} / M_{Ni} \]

where \( Z_{eq} \) is a substitute for \( Z \) for a multielement medium. With the assumption that \( Z_i / M_{Ni} \) is a constant for low-Z elements,

\[ Z_{eq} = \sum_i W_i Z_i^{1.5} \]  

Equation (14) shows the strong dependence of the \( Z_{eq} \) of a medium on the constituent element with the highest atomic number. This dependence can be used to determine the concentration of a high-Z element in a matrix of low-Z elements, e.g. the percentage of Fe in iron ore, ash in coal, etc. (\%Fe or \%ash are proportional to \( Z_{eq} \)).

**Practical Methods of Density and \( Z_{eq} \) Measurements**

When there is access to both sides of the medium under investigation, the density and \( Z_{eq} \) are determined by measuring the direct attenuation of \( \gamma \)-radiation passing through the medium. A collimated \( \gamma \)-ray beam of energy greater than 300 keV is employed for density measurements. The \( \gamma \)-ray sources used are usually 60-Co and 137-Cs. By using \( \gamma \)-rays of both low energy and high energy in a medium with a high photoelectric absorption coefficient, one can determine both the photoelectric and Compton absorption coefficients of the medium and thus \( Z_{eq} \) from Equation (13).

When only one side of the medium is available, e.g. boreholes, roads or thick walls, the detector and the source are placed on the same side of the medium. Shielding is used to stop the \( \gamma \)-rays from the source reaching the detector. Figure 3 shows schematically the geometry suitable for this application together with the \( \gamma \)-ray energy spectrum recorded by the detector. The \( \gamma \)-rays from the source undergo successive Compton scattering, losing energy. The \( \gamma \)-rays can reach the detector after one or multiple scatterings. Below 300 keV the photoelectric absorption increases with decreasing \( \gamma \)-ray energy. This spectrum is called the backscattered spectrum. It ranges from almost the source energy down to an energy at which photoelectric absorption reduces the spectral intensity to almost zero. The high-energy region of the spectrum, above 300 keV, is a function of the electronic density of the medium, and below 300 keV both photoelectric and Compton effects are present. Theory shows that the ratios of the count rates recorded in two energy windows, at high and low energy, is a function only of the \( Z_{eq} \) of the medium. Borehole logging techniques for the determination of Fe grade in iron ore deposits or ash in coal have been developed on this basis.\(^{(4,5)}\)

### 4 NATURAL \( \gamma \)-RADIATION

All rocks and soils contain a great number of radioactive elements that emit \( \gamma \)-radiation. The three main sources of natural \( \gamma \)-rays are potassium, decay products in the uranium series and decay products in the thorium series.

Of the three naturally occurring isotopes of potassium, only \(^{40}\)K is radioactive; it has a half-life of \( 1.28 \times 10^9 \) years and isotopic abundance of 0.0118%, which gives a specific activity of 31.4 Bq per g of natural potassium. \(^{40}\)K decays to \(^{40}\)Ca and emits a \( \gamma \)-ray of energy 1.46 MeV. Because many rock-forming minerals contain potassium, it is the commonest natural \( \gamma \)-ray encountered in nature. \(^{238}\)U and \(^{235}\)U are more abundant among the isotopes of uranium, with \(^{238}\)U making up 99.3% of the total. Each isotope of uranium decays by \( \alpha \)-emission to an isotope of thorium. Thorium and its daughters are also radioactive and a decay chain of the parent isotope is produced. \(^{238}\)U has a half-life much longer than its radioactive decay products, and in an undisturbed medium a secular equilibrium is established. A radioactive decay series is said to be in a state of secular equilibrium when the number of atoms of each daughter being produced in the series is equal to the number of atoms of that daughter being lost by radioactive decay. \(^{214}\)Bi is one of the isotopes produced in the \(^{238}\)U chain and decays emitting a 1.765 MeV \( \gamma \)-ray. This \( \gamma \)-ray can be used for the determination of uranium concentration in a uranium deposit if the deposit is in equilibrium. Uranium is widespread in the environment. Most crustal rocks contain some uranium, averaging about 2.7 ppm or 33 Bq kg\(^{-1}\). Phosphate-bearing rocks used as fertilizer contain high concentrations of uranium. It is also found in high concentration in oceans, ranging from about 2 to 3.7 mg m\(^{-3}\).

\(^{232}\)Th has a decay chain similar to the decay chains of uranium. One prominent \( \gamma \)-ray of energy 2.6 MeV, emitted by the daughter product \(^{208}\)Tl, is usually used for the determination of thorium concentration. Like uranium, thorium is widely found in rocks. The average thorium content of the continental upper crust is 9–10 ppm, about four times greater than that of uranium. However, having lower activity than uranium, the radioactivity concentration of thorium and uranium is about the same. High concentrations of thorium (\( \geq 10\% \)) are found in monazite, a rare-earth mineral. Owing to its high level of radioactivity, people living close to monazite sands can be exposed to high doses of radiation.

Measurement of natural radiation has found many applications. Because of the high level of natural...
radioactivity in shales it is used to distinguish between shales and other sediments. It is also used in the exploration and mining of uranium. A technique to determine the ash content of coal on conveyor belts has also been developed. It is based on the fact that uranium, thorium and potassium are associated with the mineral matter in coal and the γ-ray activity of coal is correlated with the ash content. An interface gauge for the simultaneous monitoring of the green liquor and red mud interface and the profile of the solids concentration has been developed for the alumina industry. It has been shown that, subsequent to the digestion of bauxite in caustic soda, traces of radioactivity originally present in bauxite remain with the red mud and the green liquor is free of radioactivity. The gauge consists of a number of γ-ray counters arranged inside a Teflon-coated steel tube, which is suspended vertically inside settling tanks.

5 SCATTERING AND ABSORPTION OF NEUTRONS

The neutron is a neutral particle having a mass approximately equal to the mass of a proton (about 1800 times the rest mass of an electron). The neutron has a magnetic moment and therefore there is an electromagnetic
interaction between the neutron and the atomic electrons. However, this interaction is small and can be neglected when studying the scattering and stopping of neutrons in matter. In the present discussion we will assume that the neutron interacts exclusively with the atomic nuclei. Consequently, neutron interactions in matter are rarer than γ-ray interactions and neutron ranges are longer.

The neutron energies are arbitrarily classified as:

- fast neutrons – above 500 keV
- intermediate – 1 keV to 500 keV
- slow – below 1 keV.

Slow neutrons are further subdivided as

- epithermal neutrons – from 0.1 eV to 1 keV
- thermal neutrons – below 0.1 eV.

5.1 Neutron Sources

The most common neutron sources used in applications are: (1) isotopic sources, (2) neutron generators and (3) nuclear reactors.

5.1.1 Isotopic Sources

Isotopic sources use (i) \( (α, n) \) reactions, (ii) photo-neutron reactions or (iii) the fission process.

Neutron Sources Based on the \( (α, n) \) Reaction
The principal reaction leading to neutron emission is the reaction: \( ^6\text{Be} + α \rightarrow ^{12}\text{C} + n \). This source consists of an \( α \)-emitting nuclide, e.g. Am, Pu, Po or Ra, mixed with beryllium. The \( α \)-emitter and the beryllium are usually in powder form and are doubly sealed in stainless-steel capsules.

Neutrons Emitted by Photonuclear Reactions
The binding energy of the last neutron in \( ^6\text{Be} \) is only 1.67 MeV, and neutrons can therefore be released from \( ^6\text{Be} \) by photodisintegration, i.e. by bombardment with γ-rays of energy 1.67 MeV or more.

Fission Sources
The spontaneous fission of \( ^{252}\text{Cf} \), which is an artificial isotope produced in nuclear reactors, is a source of neutrons. The Cf nucleus splits spontaneously into two fission products and emits one or more neutrons.

5.1.2 Neutron generators

Intense neutron radiation can be obtained by bombarding various targets with charged particles from a Van de Graaff accelerator or from a cyclotron. Commercially available neutron generators use one of the following reactions: \( ^2\text{H} + ^2\text{H} \rightarrow ^3\text{He} + n \) (D–D reaction) or \( ^2\text{H} + ^3\text{H} \rightarrow ^4\text{He} + n \) (D–T reaction). Neutron generators based on these reactions produce neutrons of energies 2.6 MeV and 14 MeV respectively.

5.1.3 The Nuclear Fission Reactor

The nuclear fission reactor provides neutron fluxes of high intensity close to the reactor core.

5.2 Interaction of Neutrons with Matter

A fast neutron suffers many interactions in the process of losing its energy to reach thermal energy. This process is called slowing down. The neutron may disappear during this process as a result of nuclear reactions when the neutron impinges on nuclei forming the scattering medium. The probability of scattering from or reaction with a single nucleus is called cross-section \( σ \). The unit for \( σ \) is the barn and is equal to \( 10^{-24} \) cm\(^2\).

There are four types of interactions that can occur between the neutron and the surrounding nuclei: (1) particle reactions \((n, x)\), e.g. \((n, α)\), \((n, p)\), \((n, n')\) (for neutrons of high energy only), (2) inelastic scattering \((n, n'γ)\) (the neutron energy must be above a threshold characteristic for each element, normally above 1 MeV), (3) elastic scattering and (4) radiative capture.

5.2.1 \((n, x)\) Reactions

A nuclear reaction involves the release of a charged particle or more than one neutron. The final reaction product cannot be the same as the target nucleus. Characteristic γ-rays are emitted and the neutron reactions can be used to identify the presence of particular elements in materials or for the determination of their concentration.

5.2.2 Inelastic Scattering

A neutron can interact with a nucleus of atomic number \( Z \) and mass number \( A \) to form a compound nucleus in an excited state of mass \( A + 1 \). The compound nucleus decays very rapidly to the ground state by emitting a γ-ray, and it then emits a neutron. The γ-rays that are produced are characteristic of the energy levels of the compound nucleus and can be used to identify the target nucleus.

5.2.3 Elastic Scattering

Elastic scattering is the most important interaction for neutrons produced by isotopic sources (average energy below 4.5 MeV). This interaction is also known as “billiard ball” scattering. Although the neutron reactions and inelastic scattering reduce the neutron population, their importance is modest by comparison with neutron scattering. Inelastically scattered neutrons can suffer large
energy loss; however, they constitute a small fraction of the neutrons slowing down to low energies. Most of the neutrons reach low energies through repeated elastic collisions. In elastic scattering, a percentage of the incident neutron’s kinetic energy is transferred to the recoiling nucleus and the neutron will have less kinetic energy after collision.

A useful quantity in the theory of the neutron slowing-down process is the percentage decrease in the neutron energy as a result of a collision. This is usually expressed as the average logarithmic energy decrement $\xi$, also known as neutron lethargy. For nuclei with mass $A > 10$, which are common in the Earth’s crust, $\xi = 2/(A + 2/3)$. For hydrogen $\xi = 1$. Typical values of $\xi$ for a few common nuclei are: H(1), C(0.158), O(0.12), Al(0.072), Si(0.070), Ca(0.049), Fe(0.035). The lethargy is used to calculate the mean number of scatterings required to slow down the neutron. For example, the average number of scatterings calculated for a few elements to slow down a neutron of 1 MeV, produced by a neutron generator, to thermal energy (0.01 eV) are: H(19), C(112), O(154), Al(290), Si(297), Fe(539). These examples show the unique position of hydrogen in slowing down neutrons. Its position is further enhanced when taking into account scattering cross-sections. Most of the nuclei abundant in the Earth’s crust have scattering cross-sections of several barns. The proton’s scattering cross-section between $10^5$ eV and 0.5 eV is about 20 barn.

The cross-section for elastic scattering, the relationship between the neutron energies before and after scattering and the theoretical expressions for lethargy are given in Appendix 1.

5.2.4 Radiative Capture

Once slowed down to thermal energies, neutrons diffuse through the medium without further loss of energy until their life is terminated by other processes such as radiative capture. In this process, the thermal neutron enters the nucleus, producing a compound nucleus in an excited state, which then decays to the ground state by the emission of one or more $\gamma$-rays that are characteristic of the capture nucleus. The radiation capture process only takes $10^{-11}$ s, which is virtually instantaneous compared with the initial slowing down and diffusion process, which may take several hundred microseconds. The product nucleus may be stable or it may decay (with a half-life of between a few microseconds and a number of years) to another product nucleus, often with $\beta$-particle emission. This is called thermal neutron activation.

5.3 Macroscopic Treatment of Slowing Down

For a moderating medium consisting of a homogeneous collection of different elements, the elastic macroscopic scattering cross-section $\Sigma_s$ can be written as $\Sigma_s = \sum_i n_i \sigma_s$, where $n_i$ is the number of nuclei of the $i$th element per cubic centimeter and $i$ represents the existing elements. The same applies to the absorption cross-section $\Sigma_a \cdot \Sigma$ is analogous to $\mu$ in $\gamma$-ray attenuation. For a beam of neutrons passing through a material of thickness $x$, $N = N_0 e^{-\Sigma x}$ where $N$ represents the number of neutrons that have had no interaction. The mean free path $\lambda$ is defined as $\lambda = 1/\Sigma$. For a neutron density of $N$ neutrons per cubic centimeter, the number of interactions per cubic centimeter is $N \Sigma$, where $\nu$ is the velocity of the neutron. The quantity $N \Sigma$ is called the flux $\phi$ and has units of neutrons per square centimeter per second. $\langle \xi \rangle$ for the moderating medium is the weighted-average cross-section taken over all $i$ nuclei: $\langle \xi \rangle = \sum_i (n_i \sigma_s \xi_i)/\Sigma_s$.

The theory of neutron slowing down and diffusion is presented in books dealing with nuclear reactor theory. It was developed by Glasstone and Edlund for nuclear reactors. The theory was later developed for nuclear logging by other authors. Neutron slowing down ends when the neutrons reach thermal equilibrium with the atoms and molecules of the medium. Once neutrons have reached thermal energies, they diffuse through a medium in the same way that one gas diffuses through another, except that their lifetime is limited by absorption. If there was no absorption, the distribution of neutron energies would follow the Maxwell–Boltzmann gas distribution law; the most probable energy, defined as the energy corresponding to the peak of the distribution curve, would be $kT$, where $T$ is the temperature in Kelvin (absolute temperature) and $k$ is the Boltzmann constant ($8.61 \times 10^{-5}$ eV K$^{-1}$). For a temperature of 25°C, $kT$ is about 0.025 eV. The neutron population is given by the diffusion equation which describes conservation of neutrons: Production + scattering in – absorption – leakage = 0.

The Boltzmann transport equation derived for gases also applies to neutrons. Solving the Boltzmann equation is not an easy task. For more accurate results, the neutrons are treated as belonging to several energy groups (multigroup diffusion theory).

6 RADIATION DETECTORS

The $\gamma$-ray detectors most commonly used in nucleonic gauges can be divided into three categories: gas-filled counters, scintillation detectors and solid-state detectors. The gas-filled counter is one of the oldest detectors for nuclear radiation. The Geiger–Mueller counter is still used in nuclear applications for its reliability and low cost. The scintillation detector is one of the most widely used detectors. Popular scintillators are NaI(Tl), CsI(Tl)
or CsI(Na) and Bi₄Ge₃O₁₂ (commonly referred to as BGO). The solid state detector is used in applications when high-energy resolution is required.

Common neutron detectors are the boron counter, based on the \((n,α)\) reaction \(^{10}\text{B} + n \rightarrow 7\text{Li} + α + γ\), the \(^3\text{He}\) detector, based on the \((n,p)\) reaction \(n + ^3\text{He} \rightarrow ^3\text{H} + p\) and special scintillators developed for neutron detection.

### 7 THE DETERMINATION OF WATER CONTENT IN SOIL AND BOREHOLES USING NEUTRONS

The principle of the determination of water content is the slowing down of fast neutrons. Fast neutrons emitted from a neutron source successively undergo the processes of slowing down, thermalization and diffusion. Hydrogen primarily determines the slowing down power of the medium, but it does not dominate its neutron transport property because of the presence of elements with very large neutron absorption cross-sections (e.g. Cl, Cd, In, Sm, Gd, B). These elements serve to keep the scattered neutrons in the vicinity of the source.

#### 7.1 Definition of Porosity

It is common to express the water content in terms of porosity. The bulk density of an ideal formation consisting of uniformly distributed, fluid-filled pores in a rock matrix is \(ρ_B = \Phi ρ_f + (1 - \Phi) ρ_{ma}\). Here, \(ρ_f\) and \(ρ_{ma}\) are the fluid and rock matrix densities, respectively, and \(Φ\) is the porosity. The porosity is given by Equation (15):

\[
Φ = \frac{ρ_{ma} - ρ_B}{ρ_{ma} - ρ_f}
\]

When neutrons travel through matter from the point source, their fluxes decrease with distance. The rate of decrease is governed by a “scaling unit”, which is a property of the medium. The scaling units are the slowing-down length \(L_s\), which is a measure of the ability of the bulk medium to reduce the neutron energy to a final energy in a given distance, the diffusion length \(L_d\) (the distance that thermal neutrons travel until they are absorbed), and the migration length \(L_m\) of the neutrons from their original state as primary neutrons to the point of their absorption in the medium. These distance variables are related by the equation: \(L_m^2 = L_s^2 + L_d^2\). Experimental data show that the values of \(L_s\) and \(L_d\) depend mainly on the porosity of the rocks. This is because there is a certain degree of saturation of the pore space by water (or hydrocarbons when applied to well logging).

A neutron moisture gauge consists of a neutron source and one or two neutron detectors. The instruments are normally calibrated in terms of porosity or water content. The shape of the calibration curve relating detector count rate to porosity or water content is influenced by source–detector distance/geometry. There are two basic approaches to measuring the porosity: the short-spaced (source–detector) sonde used for soil moisture determinations and the long-spaced sonde used for borehole logging.

### 8 THE MONTE CARLO METHOD

The Monte Carlo method is a numerical procedure based on statistical theory. It is used to calculate the distribution of \(γ\)-rays or neutrons produced by one or more \(γ\)-ray or neutron sources in a medium of known chemical composition. Particle fluxes and response functions (reaction rates) in selected volume elements can be calculated with fair accuracies. The technique is useful in the design of nucleonic gauges to predict the optimum source–detector–shielding configuration. The gauge response for a particular configuration can be tested in a short time at low cost on PCs using Monte Carlo calculations. Thus, tedious, time-consuming and expensive laboratory measurements can be bypassed.

The concept of the Monte Carlo technique is tracking the transport through matter of neutrons or \(γ\)-rays by simulating the statistical nature of the interaction processes. This is based on the fact that the macroscopic cross-sections may be interpreted as a probability of interaction per unit distance traveled by the neutron or \(γ\)-ray. In Monte Carlo calculations, a set of neutrons/\(γ\)-rays histories is generated by following individual neutrons/\(γ\)-rays through successive collisions. The locations and results of collisions are determined from the range of possibilities by sets of random numbers. A large library of experimental nuclear data is used in the program to select the random numbers that influence the particle history. These include the direction of the first flight on leaving the source, the choice of interaction from those possible at each collision, the mean free path between collisions and the angle of emergence after collision. Tracking the particle finishes if the particle is either absorbed, passes a lower energy limit set by the user or crosses an outer boundary. Then the history of a new particle starts. In order to decrease the statistical errors of predictions obtained from Monte Carlo calculations, the tracking of many particle histories is needed. This is becoming more and more affordable, in both time and cost, with the advent of the new generation of powerful PCs. Codes for Monte Carlo calculations on PCs are readily available and
the technique has become a powerful tool in nucleonic gauge design and nuclear applications.

9 NUCLEAR TECHNIQUES FOR IN SITU ANALYSIS

Nuclear logging is well established and used routinely in the oil, gas, uranium and coal industries. It is essential for the oil and gas industries, in which very deep holes are drilled (thousands of meters). Owing to the deep penetration of $\gamma$-radiation and neutrons, nuclear logging can locate the presence of oil or gas behind the well casing.

The laboratory analysis of core samples retrieved from boreholes and nuclear logging are complementary. Although the core can provide all the information that can be extracted from a borehole, nuclear logging is able to provide information almost instantaneously. The volume of rock sampled by nuclear borehole logging is also much larger than the core samples and thus provides better sampling statistics, especially in heterogeneous deposits. There are a number of books published in this field: Hallenburg, Hearst and Nelson, Tittman, Ellis. There are other books dealing with more specific aspects of nuclear logging. More recently, review papers have been published by Ellis et al., Mills et al., and Borsaru.

Nuclear borehole logging techniques are either passive (natural $\gamma$) or active. In passive logging, the natural radiation in the borehole is measured by an appropriate detector, whereas in active logging an artificial radioactive source provides the radiation measured by the detector. Figure 4 shows a schematic diagram of a basic borehole logging system for nuclear logging. The borehole logging tool shown in the figure is fitted with one radiation detector. The source can be either a $\gamma$-ray source or a neutron source. In the absence of the source the tool is used for passive logging. Nuclear logging can be classified according to the radioactive source employed in the logging tool.

9.1 Passive Logging – Natural $\gamma$-Ray

The $\gamma$-ray spectral log technique provides a spectrometric measurement of the $\gamma$-radiation of rocks whereas the $\gamma$-log measures the intensity of the total natural $\gamma$-radiation.

---

**Figure 4** Schematic representation of a nuclear logging system.
of the rock. These techniques have widespread applications in petroleum and uranium exploration, potash, phosphate, coal, heavy minerals, iron ore and other mineralizations. In the γ-ray spectral log, the potassium, uranium and thorium components of the natural radiation are determined and the K, U, Th, U/K, Th/K and U/Th measurements are used for borehole lithology determinations and correlations. A review of γ-ray spectral logging has been written by Fertl.\(^\text{16}\)

### 9.2 Active Logging

The backscattered γ-ray technique was developed for measuring the rock density, providing information on the type of rock encountered by the borehole, and in special cases for grade control. Figure 5 shows schematically a backscattered γ-ray spectrum obtained with a \(^{60}\)Co γ-ray source. The backscattered spectrum is dependent on the intensity and energy of the primary γ-ray source employed in the logging tool and the type of rock intersected by the borehole. Czubek\(^\text{(1)}\) reviewed the theory of γ–γ logging. The theory shows that the spectral intensity at high energy (>180 keV) is determined by the electron density, and at low energies by both the electron density and \(Z_{eq}\) (see Equations 13 and 14). The count rate in the density region is related to the bulk density of the rock interrogated by the γ-radiation. The physical basis for the density measurement is that the Compton cross-section per electron is essentially independent of the atom in which the electron is bound, and in this energy region the only interaction of consequence is Compton scattering. The electron density is directly proportional to bulk density. The ratio of counts recorded in energy windows at high and low energies is proportional to \(Z_{eq}\). Since \(Z_{eq}\) is strongly dependent on the element of highest atomic number, e.g. Fe in iron ore, even a small variation of that element in a low-atomic-number matrix will cause significant variation in \(Z_{eq}\). This is the principle of determining Fe grade in iron ore, or ash in coal, by the γ–γ technique. Mathew and Anderson\(^\text{17}\) have shown that the ratio of count rates in two energy windows at high energies (>500 keV) is proportional to the borehole diameter. In order to extract the most information from the backscattered γ-ray spectrum, the γ–γ logging must be spectrometric and automatic gain stabilization must be incorporated in the system.

Prompt γ neutron activation, neutron inelastic scattering and neutron activation are useful techniques in borehole logging. They require the use of a neutron source. The type of technique chosen depends on the particular application, the nuclei involved and the energy of the neutrons. When the neutron source is a neutron generator, both neutron inelastic scattering and prompt γ neutron activation can be performed simultaneously with the neutron generator operating in a pulsed mode. This technique is largely used in oil well logging.

### 9.3 Oil Well Logging

#### 9.3.1 γ-Ray Source

The bulk density of rock formations is an important parameter in oil well logging. The new generation density-logging tool, the litho-density tool, measures both the formation’s bulk density and its photoelectric absorption, using a \(^{137}\)Cs γ-ray source. This is carried out by recording the count rates in the Z-sensitive and density regions of the backscattered γ-ray spectrum shown in Figure 5. The photoelectric absorption \(P_e\) gives a measure of the average atomic number of the formation, which provides an indication of the lithology (sandstone, limestone, dolomite, etc.). The tool has two detectors at different spacings from the γ-ray source and has gain stabilization. Porosity can also be determined from the bulk density and \(P_e\).
9.3.2 Neutron Generator

The neutron generator is well established in oil well logging. Owing to the high energy of the neutrons produced by the generator (14 MeV), the depth of investigation is greater than that for radioactive neutron sources. It can also excite many nuclear reactions that cannot be produced by steady-state sources. However, probably the most important feature of the neutron generator is that it can be pulsed, and this allows the development of special techniques that cannot be achieved with radioactive sources.

Neutron Die-away or Neutron Lifetime

This is an old technique developed for the determination of the chlorine content of formation fluid. A pulsed neutron source is needed and the neutron generator is an ideal one. The basis of this technique is to measure the change in neutron flux with time after a neutron burst. The fast neutrons emitted during the short neutron burst are slowed down to thermal energy and diffuse in the formation. They die when absorbed in a capture process by nuclei from the formation, and capture γ-rays are released. The number of capture γ-rays is proportional to the number of thermal neutrons present in the formation. The determination of neutron die-away is based on measuring the ratio of γ-ray count rates at two different times after the fast neutrons produced by the burst have decayed to thermal neutrons. The die-away log provides information to distinguish oil (low-capture cross-section with resulting slow γ-ray die-away rate) from saline water (high-capture cross-section and fast die-away rate) behind the steel casing in wells.

γ-ray Spectroscopy Using a Neutron Generator

Using a neutron generator in a pulsed mode makes it possible to separate the γ-rays released by neutron inelastic scattering from the γ-rays generated by the neutron capture process. Inelastic scattering γ-rays are emitted within a few nanoseconds of the fast neutron interaction and occurs during the neutron pulse. Capture γ-rays are produced after tens of microseconds by thermal neutrons traveling through the formation. Figure 6 shows schematically the gate timing of this tool. The tool is used to measure the carbon/oxygen and calcium/silicon ratios. By measuring both ratios, one can distinguish carbon in calcium carbonates from that in hydrocarbons and thus the presence of oil can be established. The energy of γ-rays released from neutron inelastic scattering with C, O, Ca and Si are 4.44, 6.1, 3.7 and 1.78 MeV respectively. A background spectrum is recorded in a time window of the same length, but with the generator turned off (see Figure 6). This is a capture spectrum and is subtracted from the inelastic spectrum.

Schlumberger developed the Geochemical Logging Tool (GLT®). This tool makes the following spectral measurements: natural γ-rays produced by K, Th and U; Al by neutron activation with a 252Cf neutron source; and elements in the rock formation measured by capture γ-ray spectrometry using a pulsed neutron generator. The tool incorporates three scintillation detectors, a 252Cf neutron source and a neutron generator. Grau and Schweitzer developed a technique capable of measuring the absolute concentration of a number of elements present in the formation. The technique assumes that the composite spectrum measured in boreholes can be represented by a linear combination of known standard spectra. The weighted least-squares method of fitting the entire spectrum with the set of standard spectra extracts the chemical composition. The measured spectrum is decomposed into elemental standards. Carbon and oxygen are not measured by the GLT® but are accounted for by the chemical combination of each element measured in the capture spectrum as a single oxide or carbonate. The tool is used to derive mineralogy and petrophysical parameters from the elemental concentrations.

9.3.3 Steady-state Neutron Sources

Am–Be is used for porosity measurements. Single-detector tools employing mostly epithermal neutron detection or two-detector neutron sondes employing thermal neutron detection are commonly used in oil well logging for porosity measurements.
9.3.4 Natural γ-Ray Spectral Logging

Natural γ-ray spectral logging provides information about the presence of clays in the formation matrix. The tendency is to replace the natural γ-ray tools recording the count rates in the three K/U/Th windows with fully spectrometric tools, which record the whole spectrum in 256 channels.

9.3.5 Measurements While Drilling

Measurements while drilling are used to gather information on the formation being drilled in real time. The detectors are mounted in the drilling string near the bit. The detectors are either scintillators or Geiger–Mueller tubes that have been ruggedized to withstand the drilling process. γ-Ray, neutron porosity and density measurement-while-drilling (MWD) tools have been developed and are widely used.

9.4 Uranium

9.4.1 Natural γ-Ray Logging

γ-Rays emitted from the uranium minerals are routinely used for both quantitative and qualitative determination of uranium in exploration or ore-body evaluation. The γ-rays are ideal to use as intrinsic indicators for uranium as they occur naturally, sample relatively large volumes of material and are simple to detect and identify. The decay series of $^{238}\text{U}$ (excluding some short-lived isotopes) is:

\[
^{238}\text{U} \rightarrow ^{234}\text{U} \rightarrow ^{230}\text{Th} \rightarrow ^{226}\text{Ra} \\
\quad \rightarrow ^{222}\text{Rn} \rightarrow ^{214}\text{Pb} \rightarrow ^{206}\text{Pb}\text{(stable)}
\]

When secular equilibrium is reached after some $10^6$ years, the activity of each isotope, except $^{206}\text{Pb}$, in the decay series is equal. Disequilibrium can occur throughout the chain if one or more of the daughter products is lost by any process other than radioactive decay. Since each daughter product is an element with its own characteristic physical and chemical properties, it may behave differently within a given environment. For example, $^{222}\text{Rn}$ is a gas. Also, the solubilities of radium, uranium and thorium differ, and preferential leaching of elements may occur.

Total γ-ray Logging This is probably the easiest logging technique for quantitative analysis. The total number of γ-rays can be recorded with either a Geiger counter or a scintillator. The logging probes are calibrated in special uranium test pits. Since this method records γ-rays from many daughters of uranium, it can only be applied for quantitative analysis if both the test pit and uranium ore body are in secular equilibrium.

Accurate Spectral γ-ray Logging The principle of this technique for the in situ quantitative determination of uranium $^{235}$ is measurement of the γ-radiation (1001 keV) produced during the decay of protactinium-234 ($^{234}\text{Pa}$) to uranium-234. In the uranium decay series, $^{238}\text{U}$ first decays to $^{234}\text{Th}$, which decays to $^{234}\text{Pa}$, which in turn decays to $^{234}\text{U}$. Because the half-lives of all three reactions are short, it is unlikely that in nature the $^{238}\text{U}$ and $^{234}\text{Pa}$ will become separated. Thus, the determination of the $^{234}\text{Pa}$ grade from the count rate of the 1001 keV γ-ray gives a measure of the $^{238}\text{U}$ grade in the ore body. This method is independent of the amount of disequilibrium in the ore body. A high resolution (intrinsic Ge detector) is necessary to measure the count rate of the 1001 keV, which is weak in comparison with other γ-ray lines in the natural γ-spectrum.

9.4.2 Delayed Fission Neutrons

Fission occurs when uranium nuclei interact with neutrons and the nuclei split into fission products, emitting neutrons. Two to three percent of the fission products are unstable and β-decay, forming other nuclei. By doing this, each fission product emits one neutron. These are called delayed neutrons and are emitted with different half-lives, between 0.2 and 50s. This is the basis of the delayed fission neutron technique for quantitative analysis of uranium and is independent of the state of equilibrium of the uranium ore body. The technique consists of irradiating the uranium ore with neutrons, removing the neutron source and counting the delayed neutrons after the source neutrons disappear.

The neutron generator is well suited for this application. The generator is pulsed and then turned off. When the neutrons produced by the generator die away, the delayed neutrons are counted. The effect of diffusion of the neutrons in the medium must be accounted for. Background subtraction is achieved using the reaction $^{17}\text{O}(n,p)^{17}\text{N} \rightarrow ^{16}\text{O} + \text{n}$.

$^{252}\text{Cf}$ is also used as a source of neutrons by shuttling the source inside the moving probe between two detectors; while one detector is counting the delayed neutrons, the source is irradiating the ore body. Owing to the much lower energy of the neutrons produced by $^{252}\text{Cf}$, no background subtraction is needed (the energy of the neutrons is below the threshold energy of the $^{17}\text{O}(n,p)$ reaction). Correction for diffusion of the neutrons in the uranium ore is necessary.

9.4.3 Prompt Fission Neutrons

The neutrons emitted immediately after fission can also be used to measure the uranium concentration. The
technique uses a neutron generator as the primary source of neutrons. An epithermal neutron detector is gated off during a neutron pulse and starts counting epithermal neutrons immediately after the pulse, while thermal neutrons are present and causing fission. The uranium concentration is determined from the ratio of epithermal neutrons to (i) thermal neutrons or (ii) thermal neutron die-away time.

9.5 Coal

Nuclear borehole logging is used routinely in the exploration for coal and its acceptance in the mining stage for coal quality control is increasing. The parameters determining the economic value of coal are the thickness and depth of the coal seams and the quality of coal. Coal quality is determined by the “raw ash” content, calorific value, rank, moisture content, volatiles and the elemental composition of the ash. These parameters are determined from the coal core in the laboratory. However, this complete information is not always needed. In many cases it is sufficient to measure only thickness, depth and the raw ash content of the coal seams, and this can be achieved by nuclear logging in “easier to drill open holes”. Natural-γ, γ–γ and prompt neutron–γ techniques are all used for coal logging. Natural-γ is used to delineate the coal seams based on the fact that coal is low in natural radiation compared with the interseam sediments.

The γ–γ Technique This technique was developed for the coal mining industry in the 1970s. It is used mostly for the delineation of coal seams based on the difference in density between coal and sediments. The ash content of the coal seams can be derived indirectly from the correlation between ash and density. Good density–ash correlations are found for many coal deposits. However, this correlation is not universal. A direct measurement of ash in coal is achieved using the spectrometric γ–γ technique. This technique relies on the fact that variations in the ash content of coal correspond to changes in $Z_{eq}$. When the ash content and $Z_{eq}$ are uniquely correlated, ash content can be measured by measuring changes in $Z_{eq}$. This is carried out by calculating the $P_z$ ratio between count rates recorded in two broad spectral windows at high and low energies in the backscattered γ-ray spectrum. This measurement requires gain stabilization.

The Prompt Neutron–γ Method for Determination of Ash in Coal Owing to its high hydrogen content, coal is an excellent medium for the neutron capture technique. The neutrons emitted by the neutron source are thermalized by colliding with the hydrogen nuclei present in coal and subsequently interact with the nuclei in the coal matrix. The basis for ash determination is the correlation that exists between ash and the main constituents of ash, i.e. Al, Si and Fe or a combination of two of these elements. Charbucinski et al. developed a method based on the neutron–γ technique for the determination of ash content, depth and thickness of coal strata. The technique was later extended for the measurement of Fe in coal.

Coal Face Ash Analyzer Coal ash determination at the coal face falls into the category of in situ determination. A portable instrument capable of monitoring the quality of exposed coal seams and differentiating between coal seams and “look-alike” coal sediments is useful for the coalmining industry. Wesolinski and de Jesus developed a technique for the determination of ash on the coal face based on the simultaneous measurement of the backscattered γ-radiation at two different energies. They developed a portable instrument that can locate the coal–seam interface and measure the ash content on the coal face. The activity of the γ-ray sources employed in the instrument was 185 MBq. Borsaru et al. developed a coal face analyzer based on the measurement of natural γ-rays. The technique relies on the correlation between the natural γ-radiation of the coal and its ash content. Another coal face analyzer based on the backscattered γ–γ technique was developed more recently by Borsaru et al. It uses two microsources ($^{133}$Ba and $^{137}$Cs) of total activity 2.2 MBq. By employing such low-activity γ-ray sources, the analyzer does not need special shielding and the user is not exposed to unacceptable levels of radiation.

9.6 Iron Ore

The backscattered γ–γ technique has been employed for the simultaneous measurement of iron grade, density and borehole diameter in wide (310 and 380 mm) dry blast holes in iron ore deposits. The primary γ-ray source was 165 MBq $^{60}$Co. The backscattered γ-ray spectrum was stabilized using a $^{60}$Co microsource. The borehole diameter was measured using the ratio (S-factor) between count rates in energy windows at intermediate energies (400–700 keV) and at high energies (700–950 keV). The source-to-detector separation was 70 cm. The iron grade determination was based on the $P_z$ technique described earlier. The accuracy for ore grade obtained in 1.5 m splits was 1.9% Fe in ore in the range from 35% to 69% Fe and 3% Fe for ores in the range of iron content 9–69% Fe.

\( \text{acts elastically with a nucleus, the relation between the} \)

\( \text{neutron energy before and after scattering, } E_1 \) and

\( E_2 \) respectively, is illustrated in Equation (20) as:

\[ \frac{E_2}{E_1} = \frac{A^2 + 2A \cos \theta + 1}{(A + 1)^2} \]

(20)

where

\( A \) is the mass of the target nucleus and \( \theta \)

is the scattering angle in the center-of-mass system. Equation (20) reveals four features of elastic scattering:

\( \text{the fractional energy loss depends only on the mass ratio} \)

\( \text{and scattering angle and is independent of energy. The} \)

\( \text{minimum possible value } E_{2\text{min}} \) of \( E_2 \) (corresponding to \( \theta = 180^\circ \)) is

\[ E_{2\text{min}} = [(A - 1)/(A + 1)]^2 \]

and is the result of a head-on collision. For \( \theta = 0 \), a glancing collision, \( E_2 = E_1 \), and no energy loss occurs. When \( A = 1 \), corresponding to collision with a hydrogen nucleus, for \( \theta = 180^\circ \) (head-on collision), \( E_2 = 0 \) and all the neutron’s kinetic energy is transferred to the recoiling proton.

The percentage decrease in the neutron energy as the result of a collision, expressed as the average logarithmic energy decrement \( \xi \), is known as neutron lethargy and is defined in Equation (21) as:

\[ \xi = \ln \left( \frac{E_{1\text{min}}}{E_2} \right) \frac{[\ln(E_1/E_2)] P(E_2) \, dE_2}{E_1} \]

(21)

where

\( P(E_2) \) is the probability that the scattered neutron will have energy \( E_2 \). When the integrations are performed, it is found that the mean lethargy increase per collision, \( \xi \), illustrated in Equation (22) is:

\[ \xi = 1 + \frac{(A - 1)^2}{2A} \ln \frac{A - 1}{A + 1} \]

The use of sensors to measure toxic gases and vapors in air has increased rapidly due to several factors, including a growing public awareness of the hazards associated with many airborne chemicals, increasing regulatory requirements for industries using hazardous chemicals, and continuous advancements in the technology and instrumentation available to measure these compounds. The principal advantage of sensor systems for toxic gases and vapors relative to traditional sampling and analytical methods, is the ability to measure chemicals over short time periods, that is, in a matter of seconds or minutes, thus providing the information necessary to protect workers from acute health effects. Modern sensor-based instrumentation provides many options for processing and storing measurements, thereby allowing extreme flexibility in evaluating exposures to toxic gases and vapors relative to ceiling limits, short-term exposure limits (STELs), or longer term average concentrations based on user selectable time periods. This extreme range of options for processing data makes sensors an attractive, and in some cases, the only alternative for measuring toxic gases and vapors in air. Most of these devices can be broadly categorized as: (1) electrochemical sensors which constitute the vast majority of devices currently available for detection of toxic gases and vapors; (2) mass sensors that are based on piezoelectric materials including surface acoustic wave (SAW) devices; or (3) optical sensors that rely on the interaction of electromagnetic radiation with an analyte, resulting in some alteration of the properties of the radiation. The most common applications of sensors for measuring toxic gases and vapors in air include industrial hygiene monitoring, confined space monitoring, process emission monitoring, and leak detection.

1 INTRODUCTION

The use of sensors to measure toxic gases and vapors in air has increased considerably since the late 1960s due to a number of factors, including a growing public awareness of the hazards of many airborne chemicals and the resulting legislation designed to protect people and the environment. However, without rapid advances made over the same time period in the area of electronics technology, the current widespread use of sensors and modern instrumentation for measuring toxic gases and vapors would not be possible. Continuous development in the area of microlithography has led to significant decreases in the size and power requirements of the integrated circuitry used to process, display, and store the data generated by sensor-based instrumentation. Improvements in microfabrication techniques have also been applied to the sensors themselves, resulting in the ability to design and fabricate sensor elements with physical features on a submicron scale. Interdigital transducers (IDTs), microelectrodes, chemically sensitive field-effect transistors (CHEMFETs), and SAW devices are just a few examples of sensing components that owe their existence to microfabrication techniques. Research and development in related fields also has led to new approaches and applications for sensing technologies, including the adaptation of optical fibers for use in sensor systems and the relatively recent introduction of biologically active materials that may be used to enhance the selectivity of many different sensing techniques. These ongoing advances in the field of sensor development have led to an increased capability to detect selectively and quantify concentrations of chemical species found in a variety of media. Given the industrial nature of our society and the large potential for exposure to a broad range of chemicals that exert toxic effects in an indiscriminate fashion, the importance of chemical sensors becomes

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd
quite clear and justifies the considerable effort devoted to developing these devices.

1.1 Defining Chemical Sensors

As a result of the diverse backgrounds of researchers engaged in sensor research, there has been some ambiguity in the nomenclature applied to the field. The terms “sensor” and “transducer” have often been used interchangeably to refer to a device which provides an electrical output signal in response to some physical quantity, property, or condition which can be measured. However, some researchers prefer to make a distinction between the transducer, which is usually defined as the element that converts one form of energy to another, and the sensor as a whole, which consists of the transducer and any associated processing circuitry needed to produce an electrical output related to the physical input. In order to address this inconsistency, in the USA the National Research Council Committee on New Sensor Technologies has adopted definitions for the following three terms: the sensor element performs the fundamental transduction mechanism that converts one form of energy into another, the sensor consists of the sensor element and its physical packaging and external connections, and a sensor system comprises the sensor and associated signal processing hardware (analog or digital) located either in the same package or discrete from the sensor itself. These definitions are consistent with those developed by others and will be used throughout this discussion.

Chemical sensors are devices designed to detect the presence and concentration or quantity of a given chemical species. These sensors can be based on any characteristic of the analyte that can be used to distinguish it from the surrounding sample media, including chemical reactivity, optical or electrical properties, and mass. The ideal chemical sensor would be an inexpensive, portable, robust device that responds selectively, accurately, and instantaneously to any concentration of a particular analyte present in any medium. In practice, however, the large number of possible chemical species (>10^6), the susceptibility of most transduction mechanisms to interfering chemical compounds and changing environmental variables, and the physical limitations of the systems needed for sample introduction and data processing all serve to make attainment of this idealized performance impossible. For these reasons, development of chemical sensor systems most often focuses on specialized areas of application, such as the detection of toxic gases and vapors in air, for which the analytical challenges and acceptable levels of performance can be more clearly defined.

Chemical sensors can be classified on the basis of different criteria, including the field of application, the type of analyte, and the physicochemical operating principle of the device. The latter criterion has been used most often and will be employed for this discussion. Using this approach in the context of detecting toxic gases and vapors, most devices can be broadly categorized as electrochemical, mass, or optical sensors. A general description of each of these chemical sensor categories will be presented as an introduction, with a more detailed examination following later in the chapter.

Electrochemical sensor systems are based upon the measurement of electrical signals that can be related to the concentration of a chemical species. These devices can be further classified as amperometric, conductometric, or potentiometric, depending on whether current, resistance, or voltage, respectively, is used as the measure of response. The most common type of electrochemical sensor is the electrochemical cell, which consists of two or more electrodes, an electrolyte, and an electrical system used to measure or control voltage or current. The category of electrochemical sensors is very broad and also includes systems based on semiconductor materials, such as CHEMFETs and ion selective field-effect transistors (ISFETs). These devices are particularly well suited for miniaturization using microfabrication techniques and the resulting small package and low power requirements yield an attractive alternative for many sensing applications.

The category of mass sensors comprises a group of devices based on the acoustic properties of piezoelectric materials. These sensors employ a set of metal transducers, which launch acoustic waves into the piezoelectric substrate at ultrasonic frequencies ranging from one to several hundred megahertz. The device will operate at some resonant frequency that is determined by the geometry of the transducers, the thickness of the material, and the orientation of the crystal structure. Any mass deposited on the surface of the sensor causes a change in the resonant frequency of the device, which can be measured electronically. The first of these devices developed became known as the quartz crystal microbalance (QCM); however, several other types of acoustic mass sensors have been described including SAW, flexural plate wave (FPW), and acoustic plate mode (APM) devices. These sensors are similar to the semiconductor-based electrochemical devices in that they can very easily be microfabricated, resulting in small sensors with low power consumption.

Optical chemical sensors are based on the interaction of electromagnetic radiation with an analyte, resulting in some alteration of the properties of the radiation. This class of devices includes optical fibers and waveguides, which can be used to transport a spectrometric source of light to the sample interface. Changes in optical properties related to index of refraction, absorbance, fluorescence,
or chemiluminescence can then be evaluated using an appropriate type of photodetector.\(^1\) Optical sensors offer many advantages, including elimination of the signal “noise” associated with the transduction mechanisms of sensor systems based on electrical phenomena.

### 1.2 Performance Characteristics

Given the diverse nature of the transduction mechanisms upon which different chemical sensors systems are based, it may seem at first to be very difficult to compare performance. However, since the fundamental application of these devices is similar, that is, the identification and quantification of toxic gases and vapors, a set of performance criteria can be developed that allows comparisons between different sensor systems to be made. Table 1 lists a number of possible quantitative performance criteria, or figures of merit, that can be used to evaluate instrumentation for measuring toxic gases and vapors.\(^9\) Each of these terms will be defined below.

Accuracy or bias provides a measure of the systematic error of a sensor and can be defined in absolute or relative terms. The absolute systematic error is simply equal to the difference between the average sensor result and the true value. For example, if the average reading, \(\bar{x}\), for a sensor used to measure carbon monoxide is 12 parts per million (ppm) when the true concentration is 10 ppm the absolute systematic bias would simply be 12–10 ppm, or 2 ppm. However, since it is generally more useful to know what the bias is relative to the magnitude of the measurement, relative systematic bias is frequently reported and is defined as follows, Equation (1):

\[
\text{relative systematic bias (\%)} = \left( \frac{\bar{x} - x_{true}}{x_{true}} \right) \times 100 \quad (1)
\]

For the previous example, relative systematic bias = \([(12−10)/10]\times100 = 20\%\). In practice, every effort is made to identify and eliminate sources of systematic bias through the use of blanks and instrument calibration.

Precision describes the reproducibility of a measurement and is most often represented by the standard deviation or coefficient of variation (CV) calculated for a series of measurements recorded under the same conditions. The sample standard deviation, \(s\), is a statistical measure defined as, Equation (2):

\[
s = \sqrt{\frac{1}{N-1} \sum_{i=1}^{N} (x_i - \bar{x})^2} \quad (2)
\]

The RSD is defined as \(s/\bar{x}\), and the CV is simply the RSD expressed as a percentage, or \(100\% \times \text{RSD}\). These measures of precision provide an indication of the random error of a measurement and can be used to define confidence intervals or to estimate levels of confidence associated with a given measurement.

Sensitivity is a measure of an instrument’s ability to detect small differences in analyte concentration. Sensitivity is the manifestation of two important sensor characteristics: the slope of the calibration curve and the precision or reproducibility of the measurement.\(^9\) For two sensors having equal precision, the one with the steepest calibration curve would be the most sensitive. The simplest definition of sensitivity is calibration sensitivity, which for linear response is independent of concentration and equal to the slope of the calibration curve \((m)\). However, the calibration sensitivity fails to account for the reproducibility of the measurement and so an alternative measure of sensitivity has been proposed. The analytical sensitivity is defined as the slope of the calibration curve \((m)\) divided by the standard deviation \((s)\) of the signal measurement. This approach offers the advantage of being relatively insensitive to amplification factors since ordinarily \(m\) and \(s\) would be affected proportionally, and also yields an estimate of sensitivity that is independent of the measurement units employed. One disadvantage of analytical sensitivity as a figure of merit results from the fact that \(s\) often varies with concentration, making the resulting estimate concentration-dependent.

The limit of detection (LOD) is defined as the minimum concentration of an analyte that can be detected with some known level of confidence.\(^9,10\) This limit therefore depends on the ratio of the magnitude of the signal to the size of the statistical fluctuations, or “noise” in the signal for sample media that do not contain any analyte (blank). Once the analytical signal exceeds the blank response by more than some multiple, \(k\), times the noise, an analyte is “detected”. A value of three is most often employed for \(k\), meaning that the minimum detectable response \((S_m)\) is defined as the mean blank signal \((S_0)\) plus three times the standard deviation of the blank signal \((s_0)\) or,

RSD, relative standard deviation; LOQ, limit of quantification; LOL, limit of linearity.
Equation (3):

\[ S_m = \bar{S}_0 + 3\bar{S}_0 \]  

(3)

The LOD can then be calculated as, Equation (4):

\[ \text{LOD} = \frac{S_m - \bar{S}_0}{m} \]  

(4)

or simply Equation (5):

\[ \text{LOD} = \frac{3\bar{S}_0}{m} \]  

(5)

where \( m \) is the slope of the calibration curve. The LOQ is defined similarly, except that a value of 10 is typically used for \( k \), Equation (6):

\[ \text{LOQ} = \frac{10\bar{S}_0}{m} \]  

(6)

This has the effect of reducing the influence of random error on the signal measurement, and therefore yields a better estimate of the true value. Thus, the LOQ is a lower concentration limit, above which it is expected that the relative influence of random error or noise on a measurement will be below some acceptable level determined by the value of \( k \) employed.

The working concentration range or operating range for a sensor system is defined as the concentration range bounded at the low end by the LOQ, and at the upper end by the LOL, above which, sensor response becomes nonlinear (Figure 1).

Operation in the range below the LOQ results in larger errors due to the proportionately larger influence of noise on the signal, while operation at concentrations above the LOL complicates sensor calibration and interpretation of results. It is therefore desirable that a sensor system have as large a working concentration range as possible in order to avoid the need either to preconcentrate samples that would be below the LOQ or to dilute samples that fall above the LOL. In general, a working range of at least two orders of magnitude is needed for a sensor system to be useful.\(^{(9)}\)

The selectivity of a sensor refers to the extent to which it responds without interference from other chemical species also present in the sample. No sensor is completely unaffected by the presence of other species, particularly those that are chemically similar to the analyte of interest. For this reason it is important that potential interferents be characterized and considered when selecting a sensor system for a given application. One way to evaluate selectivity for a sensor is by evaluating the relative response of the sensor for the analyte of interest and any interferents likely to be present. The relative response \( (S_r) \) is defined as the sensitivity of the sensor for the analyte of interest \( (m_a) \) divided by the sensitivity for the interferent \( (m_i) \), Equation (7):

\[ S_r = \frac{m_a}{m_i} \]  

(7)

A large value of \( S_r \) is indicative of better selectivity. For example, if a sensor system is to be used to measure hydrogen sulfide (analyte) in the presence of carbon monoxide (interferent) and \( S_r \) is reported to be \( 10^4 \), this means that the response of the sensor to hydrogen sulfide is \( 10^4 \) times that of carbon monoxide. Thus it would require \( 10000 \) ppm of carbon monoxide to produce a response equivalent to \( 1 \) ppm hydrogen sulfide. In this case, it is unlikely that the presence of carbon monoxide would significantly interfere with the measurement of hydrogen sulfide and the sensor could be considered selective. However, for many analyte-interferent pairs, \( S_r \) may be much smaller or even less than one, in which case the sensor is not selective and an alternative method of analysis may be required.

In addition to these quantitative criteria, there are a number of other important characteristics that are used to evaluate sensor system capabilities for a given application (Table 2). One of the most important of these is response time, \( t_r \), which is frequently defined as the time required for the sensor response to reach some fraction (typically 90%) of the final value. Response time is an important consideration for compounds that are extremely toxic, since it would obviously be important to detect these as quickly as possible. In this case a response time on the order of seconds would be a requirement, while for less critical applications such as process monitoring, a slower response time on the order of minutes may be satisfactory. Another important consideration for selecting sensor

systems is ease of use. Instruments vary widely in how they are packaged and in what types of feature are offered, including how data is displayed and stored, and how the instrument is calibrated for use. A related characteristic is the skill required to operate the instrument—the utility of a sensor system is decreased significantly if highly skilled operators are needed in order to obtain useful results. Finally, cost is always an important factor in selecting a sensor system, and again instruments can vary widely in the costs associated with operation. These costs can include periodic replacement or factory recalibration of the sensing element itself, consumables such as pre-filters or other sample handling accessories, and the gases required for calibration and quality control.

### 1.3 Defining Toxic Gases and Vapors

Toxic gases and vapors are by definition compounds that adversely affect living organisms. However, Paracelsus noted in the 1500s that all substances are poisons and that only the dose differentiates a poison from a remedy, making the task of defining toxic substances somewhat more complex. Despite Paracelsus’ enlightened view, a smaller but growing subset of readily recognized toxic compounds has developed with time, often as the result of some unfortunate encounter, or more recently, based upon epidemiological study or through the use of improved laboratory techniques for assessing the toxicity of various substances. This combined pool of human experience has lead to the development of a number of lists of known toxic chemicals, and in some cases, recommended exposure levels below which it is expected that the incidence of adverse health effects will be very low. For example, the American Conference of Governmental Industrial Hygienists (ACGIH) publishes an annual listing of threshold limit values (TLVs) which refer to airborne concentrations of chemical substances to be used as guidelines in the control of health hazards in the workplace. In addition to voluntary consensus standards such as the ACGIH TLVs, governmental agencies are frequently charged with developing legal standards applicable to toxic gases and vapors, which typically requires first developing a list of regulated substances. As part of legislation known as the Clean Air Act (CAA) of 1970 and CAA Amendments of 1990, the United States Environmental Protection Agency (USEPA), was charged with developing a list of hazardous air pollutants (HAPs) that are to be regulated. This list, which now consists of 188 toxic air pollutants, includes numerous gases and vapors such as benzene, hydrogen sulfide, formaldehyde, and vinyl chloride. The Occupational Safety and Health Administration (OSHA) is another US governmental agency that promulgates standards for a number of toxic gases and vapors in the form of both substance-specific standards which outline the legal concentration limits (permissible exposure limits or PELs) and practices and procedures for working with various chemicals, and a set of tables (known as the Z-Tables) which outline the OSHA PELs for numerous chemicals.

In reviewing the lists of chemicals considered to be toxic by different government agencies, the shortcomings of this approach to regulating human exposure becomes apparent. Organizations may focus on different aspects or characteristics of a chemical’s toxicity according to the mission of that particular agency. For example, OSHA regulations are specifically designed to protect workers from exposures to chemicals arising out of their employment, and therefore focus on chemicals that historically have been of some importance in industry. The USEPA on the other hand, considers toxicity from a comprehensive environmental perspective and attempts to evaluate all mechanisms of exposure. These different approaches can yield lists of regulated toxic chemicals that are not consistent from agency to agency. This result reflects the compromises that must be made in developing finite lists of toxic compounds for the purpose of regulating exposures according to the goals and philosophy of a particular organization or government agency.

An important ramification of this regulatory approach is that efforts to control exposures are likely to be the greatest for chemicals that have been defined as toxic materials by regulatory agencies, despite the fact that there may be other equally toxic chemicals that have not yet been added to a list. Since regulatory processes typically take place in a political environment, decisions to include or exclude chemicals are not always made in a timely fashion, and neither are they always based entirely on sound toxicological data. Additional factors such as the nature of the expected adverse health effects, the number of people potentially exposed, and the feasibility and economics of controlling exposures may also be considered and can dictate whether a particular substance becomes regulated. Inclusion on a regulated list of substances can also have a significant impact on efforts to develop instrumentation for measuring a
particular toxic substance. If a large number of industries suddenly become legally and economically responsible for complying with a new regulation for a particular chemical, the demand for instrumentation to measure that chemical can increase sharply in a very short time. This logical chain of events demonstrates the interrelationship between regulatory processes and the development of sensor systems and re-emphasizes the implications of the necessarily subjective process of defining toxic chemicals.

Chemicals that have through some means been identified as toxic can be further classified in a number of ways, depending on the application of interest. For example, toxic chemicals can be grouped by their target organ (liver, kidney, reproductive), effects (CNS (central nervous system) depression, liver injury, cancer), or physical state (gas, liquid, solid). Another characteristic of toxic chemicals that has relevance both in evaluating exposures and in developing regulatory limits, is the temporal relationship between exposure and toxic response. Acute effects are those that occur almost immediately and can be reversible or irreversible. Chronic effects on the other hand are those that have a very long latency period and may require 20 to 30 years before being observed. Exposure limits for acute toxins are usually based on a relatively short sampling period, for example, the ACGIH STELs are defined as a 15-min time weighted average (TWA) air concentration that should not be exceeded at any time during the workday. Ceiling limits, which are defined as concentrations that should never be exceeded during any part of a workday, are another type of limit developed specifically for controlling exposures to chemicals that exert acute health effects. While STELs and ceiling limits are generally employed to protect from reversible acute health effects, concentrations defined as immediately dangerous to life or health (IDLH) have also been developed for many toxic gases and vapors and are designed to protect from irreversible acute health effects. IDLH concentrations refer to conditions that: (1) pose an immediate or delayed threat to life or (2) would cause irreversible adverse health effects, or (3) interfere with an individual’s ability to escape unaided from a hazardous situation.

Sensor systems are particularly well suited to evaluating exposures to toxic chemicals that exert acute health effects since they generally can provide near-real time results. Traditional analytical techniques, which involve collecting an integrated sample over some period of time, followed by laboratory analysis, do not provide the immediate feedback needed to make decisions regarding exposures to acute toxins. In addition, modern sensor-based instrumentation typically provides many options for processing and storing measurements, thereby allowing extreme flexibility in evaluating exposures relative to ceiling limits, STELs, or longer term average concentrations based on user selectable time periods. It is this extreme range of options for processing data that makes sensors such an attractive alternative for measuring toxic gases and vapors.

2 SENSOR TYPES

In this section a more detailed description of the most common types of sensor will be presented. Devices will be generally categorized as electrochemical, mass, or optical sensors, and the operating principles and important characteristics of each type will be described.

2.1 Electrochemical Sensors

The vast majority of chemical sensors currently available for detecting toxic gases and vapors are based upon electrochemical principles. Instruments employing these devices are available in a range of sizes, including those designed for both personal and fixed-point sampling, and there are hundreds of makes and models available. Electrochemical sensors include those that employ electrochemical cells, as well as solid-state devices based on semi-conducting properties of the sensing elements. These sensors can be subcategorized according to the type of electrical quantity measured, that is, if voltage is the measure of response, then the device would be referred to as a potentiometric process. Likewise, sensor systems that use current or resistance as the measure of response would be categorized as amperometric, or conductometric processes, respectively.

The most common type of chemical sensor is the electrochemical cell, which consists of two or more electrodes, an electrolyte, and an electrical system used to measure or control voltage or current. One of the electrodes is an indicating electrode which is designed to interact selectively with the chemical of interest, while the second electrode serves as a reference by providing a relatively constant potential during the measurement. In a three-electrode design (Figure 2), the working or sensing electrode usually consists of a catalytic metal such as platinum. Analytes diffuse through a porous barrier into the electrolyte and, depending on the voltage at the sensing electrode, may be oxidized or reduced. The electrons involved in the oxidation/reduction process will flow through the cell and constitute the output of the sensor. A reference electrode that is usually not exposed to the analyte provides a stable electrochemical potential in the electrolyte for comparison with the sensing electrode. The counter electrode is provided to complete the circuit, and is adjusted so that a current that is exactly equal but opposite to the working electrode will result. The concentration of the analyte is related to the

Voltage or current depending on how the electronics of the sensing system are designed.

Sensors based upon electrochemical cells are generally limited to use for detecting reactive inorganic chemicals; however, this class encompasses a broad range of contaminants that are frequently encountered in industrial workplace settings. Table 3 lists a number of toxic contaminants for which electrochemical cell-based sensor systems are available.

The specificity of electrochemical cell-type sensors can be quite good for a wide range of toxic gases and vapors. Selectivity is generally best for amperometric cells as a result of the ability to vary the voltage at the sensor electrodes, thereby controlling the extent to which analytes are polarized. This approach would more correctly be referred to as voltammetry, which is defined as the measurement of current in a cell as a function of the applied voltage. Through careful selection of the electrode system, catalysts, electrolyte, the voltage applied to the electrodes, and the polymer membrane through which the analyte diffuses, a considerable degree of selectivity can be obtained.\textsuperscript{10} These types of sensor are generally stable, can have long service lives, require very little power, and for certain toxic gases may have LODs on the order of 0.1 ppm. The greatest limitation of electrochemical cell-type sensors is the effect of interfering gases on measurements. Despite the previously cited techniques for maximizing specificity, it is not possible to obtain complete selectivity and interfering compounds may cause positive or negative cross-sensitivities depending on the electrochemical nature of the analyte of interest.

Instrumentation employing electrochemical cell-type sensors is widely available and has been continually improved over the years as a result of developments in microprocessor technology and increasing capabilities for miniaturization. Most manufacturers offer small lightweight battery-operated versions of their instruments that can be equipped with multiple sensors, thus allowing a single instrument to monitor several toxic gases simultaneously (Figure 3). This approach allows users to switch out sensor modules and affords a great deal of flexibility for addressing different monitoring scenarios. One of the most common applications of this type of instrument is confined space monitoring for which a typical instrument set-up might include hydrogen sulfide, carbon monoxide, combustible gas, and oxygen sensors.

Several types of electrochemical sensor are based on conductometric processes, which involve changes in resistance of a sensing element in relation to the concentration of an analyte. One of the most common devices of this type is known as a catalytic sensor, or pellistor, and is frequently employed in instrumentation.
designed to measure concentrations of combustible gases and vapors.\(^8,\)\(^{15}\) The principle of operation for the catalytic sensor is relatively simple. A wire coated with a catalyst is heated to an elevated temperature, which causes combustible gases to be oxidized. The resulting generation of heat changes the resistance of the wire, which is configured as part of a Wheatstone bridge circuit in order to measure the response (Figure 4). In these simple devices, the wire coil is used both to heat the sensor and as the resistive sensing element. The wire typically consists of a platinum coil embedded in a pellet of a catalytic material such as ThO\(_2\)/Al\(_2\)O\(_3\), which is also coated with a porous catalytic metal, for example, palladium or platinum. The catalyst reduces the temperature at which combustion takes place, which serves both to minimize energy requirements and to reduce the rate at which the platinum coil deteriorates as a result of evaporation.\(^{15}\) Although playing an important role in the process of detecting an analyte, the catalyst is susceptible to “poisoning” as a result of the deposition of solid decomposition products on the surface of the sensor or from irreversible adsorption of certain materials. Silicones, tetraethyl lead, and organic phosphorus compounds are frequently cited as materials that can poison catalytic sensors.

Although catalytic sensors have found wide use in combustible gas indicator (CGI) instruments, their use for measuring toxic gases is limited as a result of two factors. First, since the sensor will respond to any chemical that is oxidized, selectivity is poor. This is actually a necessary characteristic for the CGI since it would be desirable to detect the presence of any combustible gases. The second factor limiting catalytic sensor use for toxic gas detection is poor sensitivity. Although these devices work well for detecting combustible gases in the range of the lower explosion limits (LELs) and upper explosion limits (UELs) for many chemicals, such concentrations are generally several orders of magnitude greater than applicable occupational exposure limits (OELs) which are based on toxicological effects rather than the danger of explosion.

Metal oxide semiconductor (MOS) sensors, or solid-state sensors, are another type of conductometric sensor used for measuring toxic gases and vapors, or as a general survey instrument. In its simplest form, a MOS sensor consists of a semiconducting material such as tin oxide (SnO\(_2\)) on a sintered alumina bead (Figure 5). A heating coil is used to control the temperature of the sensor and a set of leads or electrodes are connected across the bead. Upon exposure to an analyte, the conductivity of the bead will change as the chemical is adsorbed due to the redistribution of electrons in the metal oxide material.\(^{15}\)
The relationship between MOS conductivity changes and temperature is complex and can be characteristic for a given chemical. This phenomenon has led to the development of arrays of MOS sensors operated at different temperatures and/or using different types of semiconducting materials in an effort to achieve greater selectivity than a single sensor could provide.\(^{16-19}\) The characteristic response patterns can be determined for a number of chemicals of interest and then used to identify and quantify unknown samples using statistical pattern recognition techniques or neural networks. MOS sensors are particularly well suited for miniaturization, given their inherent use of semiconducting materials, and are easily incorporated into integrated circuits.\(^{20}\) This means that fairly large arrays of sensors can be fabricated on a single chip, resulting in a very small size and minimal power requirements. Despite these promising developments, commercially available versions of MOS sensors are generally limited to the simplest form first described, and are most often used as a broad-range screening tool for detecting the widest possible range of toxic and combustible gases.

Sensors based on conducting polymers represent a relatively new approach involving a conductometric process for measuring toxic gases and vapors.\(^{21,22}\) These sensors are based on the use of conducting polymers or polymer composites that are placed between two electrodes. The electrical resistance of the polymer is then monitored and used as the measure of response. When the sensor is exposed to a chemical, the resistance across the polymer changes due to the absorption of the analyte in the polymer. Responses are generally rapid and reversible and power requirements are small, making this sensor an attractive approach to measuring toxic gases and vapors. The polymers used can consist of electrochemically prepared or “grown” conducting polymers such as polypyrrole, polyaniline, and polythiophene. Alternatively, conducting polymer composites have been fabricated by mixing carbon black with various insulating polymers such as poly(vinyl acetate), poly(N-vinylpyrrolidone), or poly(styrene).\(^{23}\) The resulting sensors are only partially selective – responses are based on the solubility properties of each analyte–polymer pair – so arrays of conductive polymer sensors are typically employed and have been referred to as an “electronic nose”. Sensitivity for polymer-based sensors can vary widely as a result of differences in the extent to which an analyte will partition into the polymer layer. In cases where sensitivity is a problem, preconcentration techniques such as the use of granular adsorbents and thermal desorption can be used.

### 2.2 Mass Sensors

Detection and measurement of extremely small quantities of mass cannot be performed with conventional analytical balances, which typically have maximum sensitivities on the order of a tenth of a microgram, and employ mechanisms that do not translate well to use in portable instrumentation. However, microsensors based on acoustic wave properties have been shown to be capable of detecting mass changes in the range of nanograms.\(^{6,8}\) This extreme sensitivity has led to extensive research examining the capabilities of many different types of acoustic wave sensors for a variety of applications including the measurement of toxic gases and vapors.\(^{7,24-27}\)

The use of acoustic waves for sensing requires a device with a means for generating the waves, circuitry for operating the device, and methods for measuring the wave characteristics of interest, which may include changes in velocity, frequency, or amplitude. A typical device consists of a piezoelectric material such as quartz, with a set of metal transducers mounted on the surface(s). The transducers launch and receive acoustic waves into the quartz substrate at frequencies ranging from one to several hundred megahertz. Changes in surface mass caused by the presence of an analyte cause the properties of the acoustic wave to be altered, resulting in measurable changes in velocity, frequency, or amplitude, that can be used as the measure of response. Different types of acoustic sensors are categorized based on the mode of operation, which is determined by the orientation of the
acoustic wave in relation to the piezoelectric substrate and the metal transducers. The most common acoustic sensor categories are thickness shear mode (TSM), which includes devices often referred to as QCMs, SAW, and FPW.\(^{(7)}\) Of these three types of acoustic sensor, the SAW device has received the most attention as a sensor for toxic gases and vapors owing to its excellent mass sensitivity, small size, and low-power requirements.\(^{(7,24,26,28,29)}\)

SAW device technology resulted from an outgrowth of the development of IDTs in the 1960s.\(^{(24)}\) The ability to fabricate IDTs on the surface of a piezoelectric material made it possible to generate a number of different types of acoustic wave, including the surface Rayleigh waves upon which SAW devices are based. The first application of SAW devices was primarily as radiofrequency (rf) filtering and processing circuit elements. However, it was soon discovered that these devices were extremely susceptible to environmental effects, which led to an examination of their use as chemical sensors.

SAW devices are produced using integrated circuit microfabrication techniques that result in a small package and low power requirements, making it possible to fabricate multiple sensors on a single sensor package (Figure 7). The mechanism of operation involves the generation of rf mechanical waves on the surface of a piezoelectric substrate such as single-crystal quartz.\(^{(7,28,29)}\) The waves are launched and received by parallel sets of thin metal electrodes (IDTs) deposited on the surface of the substrate. Application of a sinusoidal voltage to alternately connected IDT electrodes causes a periodic electric field to be imposed on the crystal substrate. This electric field gives rise to a periodic strain field due to the piezoelectric effect resulting in the production of a standing SAW.\(^{(7,26,28,29)}\) The wavelength and the frequency of the SAW are determined by the spacing of the IDT electrodes and the velocity of the wave in the substrate. Typical SAW device operating frequencies range from 30 to 400 MHz.\(^{(7)}\)

SAW devices can be used as chemical sensors provided that two conditions are met. First, the target analyte must be trapped on or near the surface of the substrate. This is usually accomplished through a chemical reaction or through sorption with a partially selective coating.\(^{(29)}\) And second, the presence of the analyte must produce a change in some property of the coating (e.g., modulus, mass, density) that results in a change in the amplitude or velocity of the SAW. SAW chemical sensors are usually employed in a dual-device configuration (Figure 6) in which one sensor acts as a reference device and a second coated or “working” sensor is exposed to the analyte of interest. This approach involves using the difference frequency of the two sensors as the measure of response, which has two benefits. First, it provides some compensation for environmental effects. For example, if a change in temperature occurs, both the reference and working sensors would be affected in a similar manner and the resulting difference frequency should be less affected than the working sensor alone. In addition, the difference frequencies, which are generally on the order of hertz to kilohertz, are much lower than the frequency of operation for the individual SAW devices (MHz) and can therefore be measured with less sophisticated electronic circuitry than would otherwise be possible. The dual-device approach can be applied to arrays of SAW chemical sensors by using a multiplex process in which a single reference sensor is used to produce a difference frequency for multiple working sensors.

**Figure 6** Fabrication of multiple SAW sensors on a single header/flow-cell. (Reproduced by kind permission of Sawtek Inc.)

**Figure 7** Typical dual-device configuration for polymer-coated SAW chemical sensor.
Figure 8 Chemical sensor array response pattern or “fingerprint” for several different vapors. (a) Perchloroethylene, (b) trichloroethylene, (c) 2-propanol, (d) 1,4-dioxane. Polymer coatings: PIB, polyisobutylene; PECH, polyepichlorhydrin; OV275, bis-cyanoallyl polysiloxane; PDPP, poly(diphenoxyphosphazine).

The use of a multisensor array comprising several SAW sensors coated with different sorptive polymers provides a means of achieving a high degree of selectivity while retaining the reversibility of a sorption process. With this approach, each sensor has only a partial degree of selectivity, but a specific vapor will produce a characteristic response pattern or “fingerprint" (Figure 8) that can be interpreted using pattern recognition techniques. Classification criteria can be established using methods such as the k-nearest neighbor (KNN), soft independent modeling of class analogy (SIMCA), or extended disjoint principal component regression (EDPCR). The selectivity of the polymer-coated sensor array can be optimized by selecting coatings that engage in different solubility interactions (e.g. dispersion, dipole–dipole, hydrogen bonding) thereby maximizing the amount of information provided by a given number of sensors.

The sensitivity of polymer-coated SAW sensors is determined by the mass sensitivity of the bare device as well as the interaction between the polymer and analyte of interest. In cases where polymer–vapor interactions are strong, sensor responses will be relatively large and it may be possible to measure the analyte directly and compare results to relevant standards such as OSHA PELs. However, for many applications, lower LODs are needed, making it necessary to enhance sensor system performance through the use of a preconcentration stage such as a thermally desorbable granular adsorbent tube. Using this approach, excellent sensitivity has been demonstrated for a variety of instruments and applications employing SAW sensor systems for measuring toxic gases and vapors.

Most research involving SAW sensors has focused on application of these devices to the detection and measurement of organic vapors, since many existing technologies, such as electrochemical-cell based sensors, are best suited to the measurement of reactive inorganic gases and vapors, rather than organic vapors. However, SAW sensor systems can generally be used to measure any gas or vapor, provided that an appropriate coating can be identified. The diversity of SAW sensor systems is demonstrated by the wide range of applications reported in the literature, including the measurement of carbon tetrachloride in process streams, carbon dioxide and relative humidity, nitrogen dioxide, 1,3-butadiene and styrene, ammonia, numerous organic vapors, and chemical agents such as...
organophosphorus and organosulfur nerve and blister agents (Figure 9).  

2.3 Optical Sensors

Optical sensors represent a subclass of chemical sensors in which electromagnetic radiation is directed to and from a sensing region that is exposed to the analyte of interest. Interaction with the sensing media causes some measurable change in the properties of the radiation that can be related to the concentration of the analyte. A light source typically consisting of light emitting diodes (LEDs), tungsten–halogen lamps, or lasers, provides the incident radiation that is directed to the sensing region. The sensing media can consist of a variety of different types of material designed to enhance selectivity, including various reagents, polymers, and biologically active materials. Technological developments in the telecommunications field have led to the availability of many different types of optical device that can be used to direct and interface electromagnetic radiation in optical sensor systems, including optical fibers, hollow cylinders, and planar structures. These devices are fabricated such that there is a difference in refractive index between the central core and outer cladding, resulting in almost complete internal reflection of optical energy. This allows a very efficient and low loss transmission of optical signals. Optical sensors offer a number of advantages relative to electrical sensors, including immunity to electrical interference, intrinsic safety, and the capability of transmitting signals over relatively large distances.

Although a wide variety of configurations have been reported, there are generally two approaches to employing optical sensors. In the first, the electromagnetic radiation is directed to the sensing region, which is typically located at the distal end of an optical fiber. The radiation interacts with the analyte and is returned to an appropriate detector through another section of optical fiber (Figure 10a). Alternatively, the same fiber can be used to transmit and receive the radiation (Figure 10b). Neither of these approaches requires direct contact between the sensing/reagent phase and the optical fiber, making it relatively easy to replace or change the sensing media in a sensor system. The second common configuration employed in optical sensor systems involves removal of the cladding from a portion of the optical structure (fiber, hollow tube, planar substrate) and replacing it by a reagent or polymer coating (Figure 10c). This approach is based on the fact that when light is reflected in an optical structure, a portion of the radiation penetrates a small distance into the less dense reflecting medium. This penetrating radiation is known as the evanescent wave, which, if absorbed by the less dense medium, results in an attenuation of the beam at specific absorption band wavelengths. Changes in the internally reflected light beam can be evaluated using a variety of optical

---

**Figure 10** Common configurations for optical sensors.
measurement techniques, including chemiluminescence, fluorescence, colorimetry, and absorption.

The light source and detector employed in an optical sensor system are related to the application and the optical parameter of interest. If signals need to be transmitted over large distances, then a high energy source such as an argon ion laser is usually required. However, laser-based sensor systems suffer from a number of limitations, including large power requirements, higher costs, possible photodecomposition of reagent/coatings, and the limited number of excitation wavelengths available.\(^{46}\) LEDs are the simplest and least expensive light source, but generally provide low power and are also only available for a limited range of wavelengths (550–1800 nm).\(^{44}\) Tungsten–halogen light sources can be used to provide higher intensities than LEDs over a broader range of wavelengths (340–2500 nm) thus providing an alternative to LED and laser sources. The detectors used in optical sensor systems are usually either a solid state diode or a photomultiplier tube. In many cases the incoming radiation may be modified by selecting specific wavelengths for detection. Solid state diodes are attractive for sensor systems, owing to their low costs and simplicity, but may not be sensitive enough for some applications. In these instances, photomultiplier tubes and photon counting can be used to enhance and quantify the signal.\(^{44}\)

The reagent or coating used in the sensing region of an optical sensor is selected to interact with the analyte such that some measurable optical property is changed. These materials can generally be categorized by whether the interaction is reversible or irreversible. Reversible processes are preferred for most sensor applications for a number of reasons, including, at least in theory, an unlimited lifetime. The most common types of reversible analyte–reagent phase interactions employed in optical sensors are (1) concentration or preferential partitioning of the analyte into an immobilized phase on the sensor, (2) reversible reactions between analyte and the immobilized reagent phase, and (3) displacement of a ligand in the immobilized reagent phase by the analyte.\(^{46}\) The first approach involves the use of partially selective coatings such as polymers into which the analyte partitions, based on the solubility properties of the polymer–analyte pair. Arrays of sensors can easily be prepared by applying different polymers, containing an appropriate dye, to the distal end of an optical fiber. The resulting bundle of fibers can then be employed as a sensor system by monitoring changes in an appropriate optical property, such as fluorescence, resulting from the partitioning of the analyte into the polymer–dye matrix.\(^{45,48,49}\) Classification techniques such as neural networks are then used to interpret the resulting response patterns and identify and quantify analytes.\(^{50,51}\) The development of reagent coatings that involve reversible reactions or displacement of a reagent-bound ligand offers the potential for highly selective optical sensors and has been the focus of much research.\(^{52}\) However, these approaches require the availability of appropriate and thoroughly characterized reaction mechanisms/pathways for every analyte, and in many cases suffer from slow response times and reagent instabilities.\(^{44,46}\)

The amount of information that can be conveyed by a single optical sensor is much greater than that of most other types of chemical sensors, owing to the ability to examine multiple wavelengths simultaneously. Although these capabilities have yet to be fully realized, numerous applications of optical sensors to the detection of toxic gases and vapors have been described, including the measurement of organic vapors, ammonia\(^{47}\) (Figure 11), nitric acid,\(^{52}\) carbon dioxide, and hydrogen cyanide.\(^{44}\) The inherent advantages of optical sensing systems are likely to make their use more prevalent in commercially available instrumentation in the future.

2.4 Biosensors

Biosensors are analytical devices that employ a biologically sensitive material to detect chemical species directly without the need for complex sample processing.\(^{53}\) Although not a separate class of sensor from the standpoint of the transduction mechanisms, the unique nature of the approach taken to sensing analytes with these devices justifies the use of a separate category. Biosensors are typically made by attaching a biologically sensitive material such as an enzyme to an appropriate transducer which converts the biochemical response into a quantifiable electronic signal. The goal of this approach

---

Figure 11 Planar waveguide optical ammonia sensor package. (Reproduced by kind permission of Industrial Scientific Corp.)
is to take advantage of the specific nature of many normal biological processes, thereby providing highly selective detection of the desired chemical species.\textsuperscript{53–55} Table 4 lists some of the more common biologically sensitive materials and transducer mechanisms incorporated in biosensor systems.

The majority of biosensors described have been based on the use of enzymes, antibodies, receptors, or whole cells as the selective media.\textsuperscript{53,54,56} Enzymes are proteins that catalyze specific chemical reactions in the body. They are found in all types of cell and although sharing a common polypeptide building block, specific enzymes vary considerably in their actual structure and catalytic role. Enzymes generally exhibit a greater degree of specificity compared to chemical catalysts. Antibodies are serum proteins produced by B lymphocytes and plasma cells in response to a foreign substance. In most cases the antibody will respond to only one substance – the antigen. In biosensors based on antibodies, the analyte can be either the antibody itself, or the corresponding antigen or a piece of the antigen (hapten). Even minor changes in the structure of an antigen can make it invisible to the antibody produced in response to the original antigen structure, thus the reactions are highly specific.\textsuperscript{54} Molecular receptors are cellular proteins that bind specific chemicals, resulting in a conformational change in the protein structure that elicits a cellular response.\textsuperscript{54} This “triggering” effect results in a biological amplification of a signal, and, when combined with the high degree of specificity, make receptors an attractive approach to biosensing. Biological cells are membrane-bound structures containing a variety of chemicals including enzymes, nucleic acids, and proteins. Higher-order organisms contain billions of cells, whereas the simplest living structures such as algae and bacteria consist of a single living cell. Even these simple cells can demonstrate physicochemical or biological changes in response to specific chemicals and are therefore potentially useful as biosensors.

The reliability of a biosensor depends on a number of factors, including how well the biological components can be incorporated into the sensor/transducer. Methods for fixing or immobilizing the biosensitive material include adsorption, gel entrapment, covalent coupling, and cross-linking.\textsuperscript{53,56} Adsorption typically involves bringing an aqueous solution of the biosensitive material into contact with a suitable solid material such as silica gel, clay, or ion exchange resin, and then washing to remove residual material. Entrapment in polymeric gels allows small analyte molecules to penetrate the sensing region without loss of the sensing material. Covalent coupling involves reactions between nonessential parts of the biological material and a chemically activated surface such as glass, synthetic polymer, or cellulose. Cross-linking agents induce intermolecular binding or cross-linking to attach biological materials to solid supports or other structures. For each of these approaches the challenges are similar – to prepare a biologically active sensor system in a way that does not alter or inhibit the original nature of the biological process.

Biosensors based on each of the main sensor/transducer platforms, electrochemical, mass, and optical, have been developed and continue to be explored at a rapid pace.\textsuperscript{53,56} Much of this work focuses on identifying appropriate biologically sensitive reagents/coatings for specific applications, and exploring immobilization techniques specific to different types of transducers. Current biosensor applications for measurement of toxic gases and vapors include both reactive inorganic and organic compounds such as pesticides, alcohols, ammonia, formaldehyde, BTEX (benzene, toluene, ethylbenzene, and xylene), and cyanide compounds.\textsuperscript{57,58} Although biosensors potentially offer greater specificity than other types of chemical sensor, there are considerable challenges remaining to be addressed before their use in measuring toxic gases and vapors can become more widespread. The majority of these challenges are related to the biological materials employed, including issues such as identifying and synthesizing selective materials for each application/analyte, overcoming stability issues and the limited shelf lives that are typical for most biological media, addressing slow response times, and developing commercially viable sensor packages and instrumentation that can be used in the field. Given the many advantages of biosensors, it is likely that significant resources will continue to be focused on the remaining challenges so that the potential of these devices can eventually be realized.

### 3 APPLICATIONS

Given the wide variety of sensor systems available for measuring toxic gases and vapors, selection of an
appropriate type is typically based on the requirements of a specific application. Applications vary considerably with regard to the objectives for measurement and the specific characteristics of each scenario, including the type of analyte(s) to be measured, the nature of the processes involved, and the physical characteristics of the sampling environment. Despite these differences, it is possible and potentially useful to categorize toxic gas sensing applications generally by the purpose of the measurement. This approach can simplify the process of selecting an appropriate sensing system for applications that require similar sensor characteristics or levels of performance. In the following section, application categories consisting of industrial hygiene monitoring, confined space monitoring, process emission monitoring, and leak detection will be considered and a discussion of the specific needs of each will be presented. Although certainly not the only categories that could be created, these are likely to comprise the majority of sensing applications relevant to the detection and measurement of toxic gases and vapors.

### 3.1 Industrial Hygiene Monitoring

Industrial hygiene is generally defined as the discipline devoted to the anticipation, recognition, evaluation, and control of worker exposure to chemical, physical, and biological hazards in the workplace. Using this definition, the measurement of toxic gases and vapors would fall under the area of evaluation of chemical hazards, and in fact, many industrial hygienists spend a significant portion of their time carrying out this activity. The focus on controlling hazards that may affect the **employees in the workplace** serves to differentiate this activity from others involving the measurement of toxic gases and vapors for reasons related to safety or environmental protection.

In evaluating worker exposure to specific chemical hazards, industrial hygienists refer to OELs. These OELs may consist of legally defined concentration limits such as the United States OSHA PELs, the United Kingdom maximum exposure limits (MELs) and occupational exposure standards (OESs), or the German Maximale Arbeitsplatz Konzentrationen (MAK) values. Alternatively, consensus or recommended standards such as the ACGIH TLVs may be referred to in cases where a legal standard either does not exist, or is less protective compared to other available standards. Most OELs are similar in that they involve measurement of the concentration of contaminants in the breathing zone of the worker, which has obvious implications for the size and weight of the equipment used to perform the measurement. OELs are generally developed to address either acute or chronic health effects of toxic gases and vapors and so are based on different sampling/averaging times. Evaluation of exposure to chemicals for the purpose of controlling exposures for the purpose of controlling acute health effects is generally based on comparison to STELs, which typically involves averaging the airborne concentrations over time periods of 15–30 min. Ceiling limits are also often employed for acute hazards and represent concentrations that are never to be exceeded during the workday. For chemicals with chronic health effects, concentrations are generally averaged over the entire work shift and reported as an eight-hour TWA.

The nature of industrial hygiene applications presents many challenges for measuring toxic gases and vapors. This results from the need to measure a wide variety of analytes selectively in the breathing zone of workers at relatively low concentrations for average times ranging from a few minutes to several hours. The implications of these requirements are significant: (1) instrumentation must be lightweight and battery powered so that it can be worn by the worker, thus allowing measurements to be made in the breathing zone, (2) the sensor(s) employed must be capable of selectively analyzing the chemical of interest in the presence of other interferences, (3) response times must be fast enough to allow useful comparisons between measured concentrations and ceiling limits, and (4) data processing and display capabilities should be such that both short-term and long-term averaging can be performed, as well as continuous comparison of measured concentrations to applicable ceiling limits. In addition to these fundamental requirements, a number of practical considerations are also important, including costs, ease of use, and calibration and maintenance requirements.

Despite these challenges, instrument manufacturers have made significant progress towards addressing the needs of industrial hygiene applications. Dozens of manufacturers offer sensor-based instruments designed to perform personal monitoring for a number of toxic gases and vapors, including carbon monoxide, hydrogen sulfide, hydrogen cyanide, ammonia, chlorine, and nitrous oxide compounds. The vast majority of these instruments are based on electrochemical sensors, and in particular, electrochemical cell sensors, and so are generally limited to use for reactive inorganic compounds. However, research focusing on development of acoustic/mass sensors, optical sensors, and electrochemical sensors for industrial hygiene applications should eventually lead to the availability of instrumentation applicable to a wider variety of analytes, including both organic and inorganic compounds.

### 3.2 Confined Space Monitoring

Confined space monitoring is one of the most important applications of sensors for measuring toxic gases
and vapors. This process generally involves the use of instrumentation to evaluate the atmosphere in an enclosed space prior to the entry of workers and during the course of any activities, to ensure that contaminants are below acceptable levels. Confined spaces are defined as any space that (1) is large enough or configured such that an employee could enter and perform work, (2) has limited or restricted means for entry and exit, and (3) is not designed for continuous occupancy.\(^{(59)}\) Examples of confined spaces include process vessels, tanks, and sewers, as well as large open pits, and excavations. In recognition of the hazards and potential for serious injury and loss of life, there are usually legally enforceable standards applicable to work that is conducted in confined spaces.

Procedures for entering confined spaces consist of a number of steps for ensuring worker safety, including identification of hazards in the following categories: (1) oxygen deficient atmospheres, (2) flammable atmospheres, (3) toxic atmospheres, and (4) mechanical and physical hazards. Sensor-based instrumentation is invaluable in evaluating hazards in the first three of these four categories. Verification of adequate oxygen is obviously important to sustain life but is also the first measurement made when evaluating a confined space for entry, since sensors used to evaluate flammable or toxic atmospheres may not function properly in oxygen-deficient environments. Atmospheres containing less than 19.5% oxygen are generally considered to be oxygen deficient. The level of oxygen in a confined space may be decreased by a number of mechanisms, including displacement by other gases, consumption by chemical or biological reactions, combustion processes, or as a result of normal respiration by the workers. Flammable atmospheres can result from the work being conducted in a confined space, including operations such as spray painting, coating, or the use of flammable solvents. Welding and cutting operations that involve the use of oxyacetylene equipment may also produce explosive atmospheres as a result of leaks. Toxic atmospheres may be present in a confined space as a result of the material stored in the space, decomposition of organic materials, the work being conducted, or the movement of toxic gases from adjacent areas into the confined space.

Instruments designed specifically for confined space monitoring are offered by many manufacturers and come in numerous configurations, with various features. However, these instruments generally have several common characteristics due to the requirements of the application. Most are relatively small, battery-operated devices, equipped with multiple chemical specific sensors. Sensor configurations vary but generally include an oxygen sensor, and some type of flammable/combustible gas indicating sensor. The capability to add additional sensors for specific toxic gases is offered by most manufacturers, and allows users to customize the instrument for their specific application. Carbon monoxide and hydrogen sulfide are two acutely toxic contaminants that occur widely in confined spaces. For this reason, the "stock" sensor configuration for a confined space monitoring application very often consists of sensors for detection of oxygen, combustible gases, carbon monoxide, and hydrogen sulfide. Electrochemical-cell type sensors are most often employed for the measurement of oxygen, carbon monoxide, and hydrogen sulfide, while a simple pellistor or MOS-type sensor may be used to evaluate combustible gases. Confined space monitoring equipment is usually equipped with alarms in order to warn workers immediately when the atmosphere becomes hazardous, based on user-definable criteria or set points. Equipment may rely on passive diffusion or active sampling with pumps in order to bring the contaminants into contact with sensors. The latter configuration allows for the use of longer probes or sampling lines, which can be lowered into a confined space to evaluate the atmosphere prior to workers entering. Once a space has been cleared for entry, smaller personal type sensor systems are often worn by workers to monitor continuously for hazardous atmospheres.

### 3.3 Process Emission Monitoring

The increased attention paid to the release of toxic gases and vapors into the environment has led to the development of numerous regulatory requirements for monitoring process emissions.\(^{(60)}\) In many cases these regulations can be satisfied through the use of continuous emission monitoring systems (CEMSs), which generally involve measuring the concentration of specific contaminants in an exhaust stack.\(^{(61,62)}\) These systems can be either in situ, which involves the use of a fixed sensor inside the exhaust stream, or extractive, in which a probe is used to extract a sample which is then analyzed using a remote sensor system. In situ systems are best suited for applications requiring measurement of a small number of toxic gases or vapors simultaneously, since standard sensor packages are available and equipment and installation costs are relatively low. Extractive systems are most often employed when a larger number of analytes are to be measured, or if the conditions inside the exhaust stream are so harsh that the use of in situ equipment is not feasible. In these cases, a remote sensor system allows for the use of a larger more sophisticated instrument, without exposure to the conditions of the process stream. Extractive systems can be more expensive than in situ ones as a result of the additional sampling lines required and the higher equipment and installation costs, but may be the only alternative for applications requiring...
SENSORS IN THE MEASUREMENT OF TOXIC GASES IN THE AIR

continuous monitoring of multiple analytes under harsh conditions.

The types of sensor used for process emission monitoring are similar to those used in other applications involving measurement of toxic gases and vapors, the main difference being the packaging and configuration of the complete systems. Systems can vary greatly in complexity from single point, single analyte systems, to multipoint systems for the measurement of multiple contaminants. Electrochemical sensors are probably the most common type of device employed for process emission monitoring, however the use of optical and piezoelectric sensors is increasing. Although generally not considered to be sensor systems, traditional benchtop analytical methods such as gas chromatography, and infrared spectrometry are also used with extractive systems for process emission monitoring. The packaging and configuration of sensor systems used for process emission monitoring depends on the requirements of the specific application. For in situ monitoring of a single analyte, a single sensor mounted in the process stream would be adequate. The output from the sensor could be displayed directly at the location or could be routed to a central control location for processing and display. Extractive systems are more likely to involve the use of multiple sensors and locations, and therefore would require more sophisticated systems for transmitting and monitoring sensor outputs.

3.4 Leak Detection

Detection of leaks or “fugitive emissions” is another important application of toxic gas and vapor sensor systems. Environmental regulations may require that leak detection be performed on a regular basis for processes involving toxic gases and vapors. Leaks may also represent a significant cost to operations in the form of lost product or raw materials, which is why many organizations perform leak testing on a routine basis. In addition, sudden leaks of acutely toxic materials can pose an immediate threat to life so operations involving these types of material may have fixed leak detection systems in place to protect from this hazard. Potential sources of leaks include valves, pumps, flange joints, fittings, pressure relief devices, vents, access doors, seals, pumps, and compressors.

There are generally two approaches to monitoring for leaks of toxic gases and vapors. The first involves mounting fixed sensors in areas where leaks are likely to occur or where the consequence of a leak is severe (see Figure 12). An example of this scenario would be the use of a fixed sensor mounted in a semiconductor processing area to detect any release of toxic gases such as arsine (AsH3). One problem associated with this approach is how to
determine the number of sensors required for a given area and where to locate the sensors, since these decisions have implications for the time it takes for a sensor to respond to a potentially life threatening leak. Alternatively, sensors could be placed at every probable leak site, for example fittings, flanges, and seals, although this method may not be feasible for operations where the number of potential leak sites is very large. The second approach to leak detection involves the use of portable instrumentation for periodic or routine examination of all potential leak sites. This method is appropriate when the consequence of a leak is less severe and when it is acceptable for a leak to go undetected for some period of time. The requirements for sensor systems employed in either of these approaches to leak testing are similar. In both cases it is desirable that response times be relatively fast (30 s or less) so that (1) in the case of life threatening releases of toxic gases, adequate warning is provided, and (2) when using portable instrumentation to screen for leaks, the operator can complete multiple measurements more quickly. Selectivity may not be important for many leak testing applications, since there often is only a single gas or vapor to be measured. However, in cases where multiple contaminants are potentially present and one or more are extremely toxic, sensor selectivity would be a paramount consideration. For applications where selectivity is not crucial, MOS and pellistor-type sensors may be employed, provided that sensitivity is adequate for the toxic gas of interest. When selectivity is important, more specific sensor systems, such as those employing electrochemical cells, coated piezoelectric, or optical sensors, could be used.

4 QUALITY CONTROL AND MAINTENANCE

Quality control is a fundamental component of most activities in business and industry, but is particularly important in the measurement of toxic gases and vapors, given the serious nature of the consequences that could result from unreliable data. For this reason, sound procedures for calibrating and maintaining sensor systems are crucial to ensure that the data obtained using these devices is of acceptable quality and that the lives and health of those affected are ultimately protected. In this section, the requirements of different toxic gas and vapor sensing applications will be considered from the standpoint of data quality, and typical procedures for the calibration and maintenance of sensor systems will be described.

4.1 Data Quality Objectives

The quality of the data obtained by different sensor systems for measuring toxic gases and vapors is likely to be variable, owing to a number of factors. Various sensing platforms have different strengths and weaknesses and are therefore likely to be better suited to certain applications. Alternatively, when employed in different manufacturer’s instruments, the same type of sensor may produce output of varying quality as a result of design differences. Another factor affecting the quality of data obtained using sensor systems is the fact that these devices are often configured in personal or portable monitoring systems, which are then employed in harsh environments. Under these conditions, it is inevitable that some sacrifices are made in terms of data quality, particularly when compared to analytical laboratory-based instrumentation. Further, even the most rigorously designed sampling and analytical methods for toxic gases and vapors have measurable levels of error and uncertainty in the resulting data, and so it is reasonable to expect these in sensor systems as well. Given these constraints, the challenge becomes one of matching the data quality objectives of a specific application to the capabilities of available toxic gas and vapor sensor systems. In the following paragraphs, the requirements of several toxic gas and vapor measurement applications will be considered and used to illustrate differences in the resulting data quality objectives for sensor systems.

4.1.1 Industrial Hygiene Monitoring

As previously described, industrial hygiene monitoring frequently involves the measurement of toxic gas and vapor concentrations in order to evaluate worker exposures by comparing results to legal limits such as the OSHA PELs. Validated analytical methods that have met specific requirements for accuracy and precision are required for this compliance monitoring. OSHA stipulated accuracy requirements for the measurement of toxic gases and vapors, are generally ±35% for concentrations at or below 0.5 times the PEL and ±25% for concentrations at or above the PEL. The National Institute for Occupational Safety and Health (NIOSH) also develops and validates methods specifically for workplace exposure assessment. NIOSH has established the criterion that on average, over a concentration range of 0.2–2 times the OEL, a method should provide a result that is within ±25% of the true value 95% of the time. (64) Validation requires a determination of the bias and precision of a method, which are then used together to calculate a confidence interval for the estimate of overall accuracy. Although the use of sensor-based direct reading instrumentation for OSHA compliance monitoring is not prohibited, the vast majority of validated methods involve collection of an integrated air sample onto sample media over some period of time, with subsequent laboratory analysis. This is probably because OELs for toxic gases
and vapors are typically in the low parts per million concentration range and thus challenge the sensitivity of sensor systems. However, there is increasing recognition of the capabilities of sensor-based direct reading instruments, particularly for evaluating OELs based on short averaging times such as ceiling limits and STELs. OSHA has validated a sensor-based instrument for the measurement of carbon monoxide and several OSHA standards, including those for ethylene oxide (29 CFR 1910.1047) and formaldehyde (29 CFR 1910.1048) specifically cite direct-reading instruments as an alternative method of analysis, thus paving the way for increasing use of sensor systems for industrial hygiene monitoring.

4.1.2 Confined Space Monitoring

Like industrial hygiene monitoring, confined space monitoring is usually conducted in order to comply with governmental regulations and so the data quality objectives are generally defined by applicable regulations. However, referring to the OSHA Permit-required Confined Spaces Standard (29 CFR 1910.146), there is little specific information given with regard to the performance of instrumentation used for detecting hazardous atmospheres. The standard simply states that before an employee enters a permit-required confined space, the internal atmosphere shall be tested with a calibrated direct-reading instrument for (1) oxygen content: 19.5–23.5%, (2) flammable gases and vapors: concentrations must be less than 0.1 times the LEL, and (3) potential toxic air contaminants: concentrations must be below the applicable PEL and/or IDLH. Without OSHA, specified levels of accuracy for the measurement of toxic gases and vapors, it seems reasonable that the general requirements for industrial hygiene compliance monitoring would be appropriate (i.e. ±35%) for concentrations at or below 0.5 times the PEL and ±25% for concentrations at or above the PEL.

In the case of measuring flammable gases and vapors, performance standards have been developed for sensor systems. The primary standard for these devices is American National Standards Institute/Instrument Society of America (ANSI/ISA)-S12.13.1-1986, which specifies that the instrument must indicate the true test concentration within ±5% of the full scale reading or ±10% of the applied concentration, whichever is greater. The standard also has performance specifications related to temperature and humidity effects, response times, and effects of air velocity, vibration, electromagnetic interference, and long-term storage. These relatively rigorous requirements are necessary due to the potentially severe consequences of failing to detect a hazardous environment, but are also more easily achieved given the relatively high concentrations to be measured – typical LEL concentrations are of the order of 1–3%, meaning that 0.1 times the LEL would be 1000–3000 ppm.

4.1.3 Process Emission Monitoring

In most instances where process emission monitoring is required by environmental regulations, data quality objectives are clearly defined and strict procedures for ensuring the attainment of these objectives are enforced. In the United States of America, the CAA Amendments, Resource Conservation and Recovery Act (RCRA), and state environmental programs are intended to reduce air pollution and provide for an accurate characterization of emissions of specific toxic substances, including many gases and vapors. The CAA Amendments apply to a variety of industries, and air emission measurements are a key part of most facility’s compliance strategies. Depending on the nature of an industry and the quantity of specific pollutants emitted, USEPA regulations may require either a CEMS or the use of manual source testing methods which involve collection of source effluent samples using filters, or other sampling media and subsequent laboratory analysis. An examination of the data quality objectives for the numerous USEPA-required measurements of toxic gases and vapors is beyond the scope of this section. However, these specifications are available in the Federal Register, and in many cases are online, so that those affected are able to gather reliable data according to USEPA regulations. The individual subparts of the USEPA rules specify the reference methods used to evaluate the accuracy and precision of CEMS and include detailed performance specifications outlining all aspects of sampling and analysis systems, including procedures and specifications for calibration and quality assurance/quality control (QA/QC).

4.2 Calibration

All sensor systems require periodic calibration in order to ensure that the resulting measurements of toxic gases and vapors meet the required data quality objectives for a specific application. This process generally involves the use of calibration or “span” gases for which the true concentration is known to some degree of certainty. The span gas is sampled and the instrument is adjusted using a span control so that the output is equal to the known span gas concentration. Span gases are readily available for many commonly encountered toxic gases at a variety of concentrations; however, the gases are consumed in the calibration process and may represent a considerable expense if the instrument is used on a regular basis. In recognition of the expense and potential complexity of calibration, instrument manufacturers have gone to great
lengths to simplify the process. Unfortunately, calibration requirements have become a part of the marketing process for instrumentation, which may result in some manufacturers making exaggerated claims regarding the acceptable amount of time between calibrations for their particular system. Although data quality objectives vary by application, for the purpose of measuring toxic gases and vapors where the consequences of unreliable data are significant, sensor system accuracy should be verified on a daily basis.

Most sensor systems are designed to be calibrated using a single span gas concentration. Calibration then involves zeroing the instrument either by sampling in an environment that is known to be contaminant-free, or using a cylinder containing “zero” air. The output of the instrument is adjusted to read zero and then the calibration gas is sampled and the span control is used to adjust the output to read the known concentration. This process which is usually referred to as a one-point calibration, actually defines the calibration curve for the instrument using two points, zero and the span gas concentration. A potential problem with this approach is that unless the instrument response is absolutely linear, some error is introduced when concentrations away from the calibration concentration are measured (Figure 13). Manufacturers try to minimize deviations from linear response through sensor design and electronic processing of sensor outputs; however, the problem still exists to varying degrees. For this reason, the selection of the span gas concentration is important and it is usually desirable to use a concentration close to the exposure limit of interest in order to maximize the accuracy of the instrument.

![Figure 13](image13.png)  
**Figure 13** Potential error introduced by using one point calibration and assuming linear response. ——, actual response; --- --- --- ---, linear response.

![Figure 14](image14.png)  
**Figure 14** Instrument with calibration kit (reproduced by kind permission of Biosystems).

Calibration kits for combustible and toxic gases are commercially available and are usually provided when an instrument is initially purchased. These kits often consist of one or more cylinders of known concentrations of specific air–gas mixtures, a pressure regulator and valve, and a hose adapter for connecting the cylinders to the instrument (Figure 14). Instruments can also be calibrated using static test-atmospheres generated in either rigid containers (e.g. glass, stainless steel) or in flexible bags (Tedlar®, Mylar®) by adding a known quantity of the chemical of interest to the known volume of air in the container. Alternatively, dynamic test-atmosphere generation systems can be used to prepare known concentrations of toxic gases and vapors; however, these approaches become increasing complex, and may not be cost effective or efficient for many users.

### 4.3 Maintenance

Maintenance is an important part of quality control for toxic gas and vapor sensor systems. Although the requirements are generally not complicated, the consequences of equipment failure can be serious or even fatal, so a proactive approach to maintenance is a crucial part of any measurement process. Maintenance tasks can be categorized by the individual components of the instrument, including items such as batteries or power supplies, sample tubing and pneumatics, filters, flashback arresters, sensors, and electronics.

#### 4.3.1 Batteries

Portable instruments usually operate on battery power and are designed to provide at least 8h of service. However, many rechargeable batteries have a memory
effect, and also eventually fail, so it is important that the
batteries have been cycled and fully charged to ensure
optimum performance.

4.3.2 Pneumatics
Many instruments contain tubing and various valves or
fittings to direct air flow. Tubing can become worn or
cracked as a result of exposure to harsh environments,
and may eventually leak, so it is important to examine
these systems both visually and functionally to determine
if they are in working order. Any pumps and valves
should also be examined for blockage or signs of
corrosion or contamination by particulates, to ensure
proper operation. Filters are often used to prevent dust
good particulates from entering a sensor system,
but may become clogged. This can cause reduced airflow
through the instrument, which may result in decreased
accuracy or detrimental effects on instrument response
time. Therefore, filter replacement should be a routine
part of instrument maintenance.

4.3.3 Intrinsic Safety Components
Sensor systems for measuring toxic gases and vapors
are often used in hazardous environments that require
an intrinsically safe design. For this reason, it is vitally
important that maintenance activities are consistent with
those recommended by the manufacturer, so that the
instrument remains intrinsically safe. Although different
manufacturers’ sensor systems may appear to be similar,
users should never interchange parts, since this can
eliminate the intrinsically safe rating of an instrument
both from a legal and practical standpoint. Flashback
arresters, if required, should be examined to ensure that
they are present and in good condition.

4.3.4 Sensors
The design and function of sensors varies significantly,
so the manufacturer’s recommendations for maintenance
should be referred to for specific guidance. In general,
instrument are often used in atmospheres containing
corrosive environments, under conditions of temperature
and humidity extremes that could damage sensors.
Although the most obvious signs of these effects is
likely to be erratic readings or complete failure, sensors
should be examined periodically for signs of corrosion,
condensation, leakage, and to evaluate the general
physical condition of the sensor assembly.

4.3.5 Electronics
Erratic readings can indicate dirty or faulty potentiome-
ters or corroded electrical connections. Oxidation of
contacts can also occur if an instrument is not used for
extended periods. Contacts can be cleaned using physical
means such as a piece of fine abrasive; however, in gen-
eral, electrical maintenance should be handled by the
instrument manufacturer.

Over the past few decades the pace of change in spectroscopic techniques has been remarkable. Spectroscopic techniques are emerging as important, powerful, and versatile tools in determining exposure levels of hazards generated in working environments. Occupational safety and health studies employ spectroscopic techniques to analyze hazardous chemicals, biomarkers, and particulate matters of exposure. In comparison with many traditional detection techniques such as gravimetric methods, spectroscopic techniques are much more sensitive, selective and accurate. The major spectroscopic techniques used in industrial hygiene include mass spectrometry (MS), scanning electron microscopy (SEM), X-ray microanalysis (XM), atomic spectrometry (AS), ultraviolet/visible (UV/VIS) photometry, fluorescent spectrometry (FS), Fourier transform infrared (FTIR) spectroscopy, and Raman spectroscopy (RS). Interest in using MS in industrial hygiene is driven by its value in understanding basic physical, chemical, and biological processes related to workers’ exposure to occupational hazards, and in devising new methodologies to monitor exposures. SEM has become particularly useful in the study of pneumoconioses and workplace environmental particles since being complemented with energy dispersive X-ray (EDX) analysis and automated image analysis capabilities. SEM and EDX have been used extensively to characterize particles found in lung tissues. Atomic spectrometric methods are used widely for occupational health evaluation of inorganic
1 INTRODUCTION

The pace of change in spectroscopic techniques has been remarkable. They are emerging as important, powerful, and versatile tools, and have increasing applications in the workplace. For occupational safety and health studies, spectroscopic techniques are primarily used to detect and analyze hazardous chemicals, biomarkers (e.g. metabolites, DNA adducts, protein conjugates, and allergens), and to investigate pneumoconioses and workplace environmental particles. They play an important role in determining exposure levels of hazards generated in the working environment, and in finding the adverse effects of exposures and their mechanisms of action. In comparison with many traditional detection techniques such as gravimetric methods, spectrometric or spectrophotometric techniques are much more sensitive, selective and powerful. The major spectroscopic techniques used in industrial hygiene studies include MS, SEM, XM, AS, UV/VIS photometry, FS, FTIR, and RS. In this article, the basic principles of these major spectroscopic techniques and their applications to industrial hygiene are described.

The interest in using MS by scientists in studies pertinent to industrial hygiene is driven by the need to understand the basic physical, chemical, and biological processes related to workers’ exposure to occupational hazards and to devise new methodologies to monitor exposures in the work environment. MS is capable of looking at the details of exposures, and as the most sensitive tool, to analyze small molecules and macromolecules in biological systems. With tandem mass spectrometry (MS/MS) techniques, MS brought special capabilities to providing specific characterization of molecular structures and to detecting target analytes at trace levels. The development of new ionization methods such as electrospray ionization, atmospheric pressure chemical ionization (APCI), and matrix-assisted laser desorption ionization (MALDI) have contributed to great strides forward in the study of biological macromolecules. The ability to ionize polar, labile and involatile species has been the fundamental basis upon which MS extends its applications. It is important for us to recognize the breakthroughs in ionization techniques of the 1980s and 1990s. These advances have allowed application of MS to progress and develop rapidly. Additionally, combining gas chromatography (GC) or liquid chromatography (LC) with MS offers the possibility of taking advantage of both chromatography as a powerful separation technique and MS as a powerful and sensitive detection and identification technique. Furthermore, Fourier transform ion cyclotron resonance mass spectrometry (FTICRMS), and a new generation of high performance time-of-flight mass spectrometry (TOFMS), which includes nanoflow electrospray hybrid quadrupole time-of-flight mass spectrometry (QTOFMS) and matrix-assisted laser desorption ionization/time-of-flight mass spectrometry (MALDI/TOFMS) technologies, are just beginning to add much needed analytical power to our arsenal for macromolecular identification and characterization. These developments will bring important methodology to scientists and thus accelerate the integration of MS into work-related research strategies. The range of applications in environmental health and industrial hygiene studies includes development of qualitative and quantitative analytical procedures, structural determination of aberrant proteins, investigation of biomarkers for exposure to hazards, characterization of allergens related to occupational asthma, and identification of microbial products in complex samples. MS and its related techniques and applications are described in section 2.

SEM is introduced in section 3. It is ideally suited to study pneumoconioses and workplace environmental particles when it is equipped with an EDX analysis system and an image analyzer (IA). Particle matter has been recognized as a cause of various lung diseases for many years. Specific pneumoconioses such as coalworker’s pneumoconiosis, asbestosis, and silicosis may result from inhalation of particles in the workplaces. SEM and EDX have been used extensively to characterize particles found in lung tissues. While it is not possible to compare a measured lung dust burden to the actual exposure due to the lack of exposure data and to particle clearance, the measured lung particulate burden does represent retained particle dose. The SEM and EDX analysis may be used for a number of applications in occupational safety and health including the analysis of particles collected on air filter samples taken from the working environment, analysis of individual particles found in bulk dusts, and in the study of pneumoconioses.
Bulk compositional analyses of respirable particulate material, and even particle-by-particle compositional analyses, may not always be sufficient to predict the level of biological activity of respirable particles or the health risks of exposure to them. Toxicants may be located on the particle surface or may be more heavily concentrated there, resulting in heightened biological availability and expression of toxic activity. Or, in some cases, surface coating materials may have a prophylactic effect on expression of the toxicity of the underlying bulk of the particle. An example of the latter effect is the modified activity of the quartz component of some mixed composition mineral dust exposures for causing mixed dust pneumoconioses. SEM with EDX or wavelength dispersive X-ray spectroscopy can provide some information about the elemental composition with depth into a particle, by acquiring X-ray spectra at two or more electron beam accelerating voltages. This method has been used to detect thin submicrometer aluminosilicate coatings or clay “surface occlusion” on respirable quartz particles. Applications of SEM to the study of pneumoconioses, including determination of lung particulate burden, particle chemistry, and respirable particle surface characterization, are described in section 3 of this article.

Atomic spectrometric methods continue to be used widely for occupational health evaluation of inorganic metals and are documented briefly in section 4. The development of ICPAES techniques has been increasing, and has been applied to elemental analysis of nearly all the elements. ICPAES offers a simultaneous or rapid sequential multielement determination capability at the major, minor, and certain trace concentration levels. It has become established as a widely accepted method for the analysis of metallic aerosols, powders of metals, dusts, and fly ashes. A vast amount of published atomic spectrometric methodology is available, covering a wide range of application areas. This is because trace elements released into the atmosphere in industrial processes have aroused great interest. Major advantages include specificity, speed, and ease of use. However, for ultratrace or trace level analysis atomic spectrometric methods have been increasingly replaced by inductively coupled plasma mass spectrometry (ICPMS). AS and its related techniques and applications are described in section 4.

Spectrophotometric detectors coupled to chromatographic separation techniques are often used to characterize the workplace environment and are discussed briefly in section 5. These techniques are employed to confirm the accuracy of direct reading instruments or when direct reading instruments are not available for the environmental contaminant, when the workplace environment is complex and contains multiple chemicals that need to be measured, for regulatory documentation of exposure levels, and for biological monitoring. Spectrophotometric detectors that are coupled to high-performance liquid chromatography (HPLC) or GC include UV/VIS, fluorescent, light scattering, refractive index, diode array, MS, infrared (IR), radioactivity, and luminescence. The choice of detector is dependent on the analyte’s spectral properties, and the required sensitivity and selectivity. Both the sensitivity and selectivity of spectroscopic detectors are dependent, in part, on wavelength(s) employed. In addition, it is desirable to choose a detector with a wide linear working range to be able to assess both major and minor chemical components in the workplace environment. In monitoring the workplace environment, the most commonly employed HPLC detectors are the UV/VIS and fluorescent photometers, whereas, the most commonly used GC detectors are the flame photometric detector (FPD) and the mass spectral detector (MSD).

With the increased use of highly toxic gas and vapor mixtures in science and industry, FTIR and Raman spectroscopies have played an important role in industrial hygiene monitoring. Although FTIR and Raman spectroscopies are similar in that both techniques provide information on vibrational frequencies, there are many differences between the two techniques. For example, some vibrations are only Raman active while others are only IR active; the vibration of a heteropolar diatomic molecule is IR active, whereas that of a homopolar diatomic molecule is not IR active. The method for determining quartz content in respirable coal dust is often based on dispersive IR or FTIR spectroscopy. Like IR, RS is a powerful technique and has a variety of applications. They are complementary, and both are utilized whenever possible. IR and Raman spectroscopies and their related techniques and applications are discussed briefly in section 6.

Finally, field-portable methods, which have received increasing attention, are summarized in section 7. Field-portable methods for monitoring airborne workplace contaminants and toxins have received increasing attention. A number of portable monitors for airborne contaminants have been commercially available for many years, but new developments may provide for on-site compliance monitoring, which has heretofore been more the exception than the rule. The ability to conduct measurements on-site in the occupational setting offers significant advantages. Field-portable methods are often desired so that decisions regarding worker protection, engineering controls, and so on can be made quickly. The capability for rapid decision-making offered by on-site monitoring can help to save costs, and also offers a means to assess, and thereby prevent, worker overexposures to toxic substances in a timely manner. Field-based monitoring is especially useful for applications in the construction industry, in agriculture, and in other situations where
2 MASS SPECTROMETRY

2.1 Introduction

The mass spectrometer is an instrument capable of producing a beam of ions by converting neutral molecules into gaseous ions, and then separating these ions according to their mass-to-charge ratio and recording the relative abundances of the separated ion species as a mass spectrum.1 Today MS has brought special capabilities to a wide variety of scientific research by providing specific analyses of substances, their metabolites, and biological macromolecules, often with structural information. The range of applications includes qualitative and quantitative analytical procedures employed in environmental health and industrial hygiene.

In instrumentation, the mass detector has been developed in a variety of types, shapes, and sizes.2–4 The selection of the detector is based on the needs of the user and its functions:1 the quadrupole analyzer is employed to provide an electron ionization (EI) or chemical ionization (CI);2 the ion trap spectrometer, which is a highly geometrically modified quadrupole analyzer, is adequate for low-energy collision;3 the ion cyclotron resonance spectrometer, which is the basis for Fourier transform MS, has high resolution;4 the time-of-flight (TOF) spectrometer, which separates ions in time rather than space and has an almost unlimited mass range, is used for detection of macromolecules; and5 the magnetic sector instrument, in which ion separation is achieved spatially by the application of a magnetic field (sometimes coupled with an electrostatic field), is suited to conduct collisionally activated dissociation at high energy. Furthermore, by coupling of two or more types of the above-mentioned mass analyzers, an MS/MS or an ion trap mass spectrometry (MSn) technique is achieved. MS/MS is a key instrumental development in analytical and bioanalytical chemistry. It is widely applied in the characterization of molecular structures and in the trace analysis of targeted analytes. The most widely used activation method is called collisionally induced dissociation, in which precursor ions are selected in the first MS of multistage MS for repulsive collisions with inert gases such as helium or argon. In addition, the coupling of MS with separation techniques and the development of new ionization methods such as electrospray ionization, APCI, and MALDI have contributed to great strides forward in this field. The ability to ionize polar, labile and involatile species has been the fundamental basis upon which MS extends its applications. It is important for us to recognize the breakthroughs in ionization techniques of the 1980s and 1990s. These advances have allowed application of MS to progress and develop rapidly.

The interest in using MS by scientists in studies pertinent to industrial hygiene is driven by the need to understand the basic physical, chemical, and biological processes related to workers’ exposure to hazards and to devise new methodologies to control exposures in the work environment. MS is capable of looking at the details of exposure, and is a highly sensitive tool for structural determination of aberrant proteins, development of biomarkers for exposures, identification of microbial products in complex samples, and characterization of hazards in occupational and environmental health evaluations.

2.2 Gas Chromatography/Mass Spectrometry

2.2.1 Principles and Instrumentation

The coupling of GC with MS was first achieved in 1957.5 It is a combination of two microanalytical techniques: a separation technique, GC, and an identification technique, MS. The gas chromatography/mass spectrometry (GC/MS) combination overcomes certain deficiencies or limitations caused by using each technique individually, and gives a two-dimensional identification consisting of both a GC retention time and a mass spectrum for each component of the mixture. This combination has several advantages. First, it can separate components of a complex mixture so that mass spectra of individual compounds can be obtained for qualitative purposes; second, it can provide quantitative information on these same compounds. GC/MS can provide a complete mass spectrum from as little as 1 pmol of an analyte, which gives direct evidence for the molecular weight and a characteristic fragmentation pattern or chemical fingerprint that can be used as the basis for identification. Although the direct GC/MS method is limited to the analysis of those compounds that can be made volatile without thermal decomposition, many compounds that are nonvolatile can be handled successfully after chemical derivatization. The instrumentation of GC/MS consists essentially of three components: the gas chromatograph, the mass spectrometer and a data system. GC/MS has developed...
into one of the most sensitive and selective analytical techniques for the separation, identification and quantification of components of complex mixtures.

The GC/MS technique has been utilized in a diverse range of applications such as toxicology, environmental monitoring, molecular biology, clinical health, and industrial hygiene, as well as many others. In these applications, the analyte is often present in a complex matrix consisting of a great number of compounds which may mask its presence or otherwise inhibit its detection. One of the most common ways in which GC/MS is used in industrial hygiene is as a diagnostic tool, which is particularly useful in the analysis of complex mixtures where the analytes are present in low quantities. GC/MS is also widely used in determining hazardous materials, derived metabolites, and protein/DNA adducts in biological fluids (e.g. blood or urine) from workers exposed to specific hazards.

2.2.2 Methodology

2.2.2.1 Sample Preparation Sample preparation is important for successful analyses by GC/MS. Industrial airborne hazards include gases, vapors, liquids, and particulates. Air sampling is of course a crucial step within the total scheme of air analysis. There are a variety of methods available for the collection of airborne particles. Generally, a method selected will often depend on the purpose for which the sample is being taken, and also depend on the type of compounds to be analyzed. A few preprocessing steps may be needed to manipulate the sample into a form ready for analysis. In addition, the physical state of sample material will affect the method to be used for the introduction of sample into the spectrometer. A wide variety of techniques are available for processing gaseous, liquid and solid samples. In industrial hygiene studies, one prevalent strategy in dealing with air samples consists of filter collection of particles, followed by an appropriate second stage adsorption of organic chemical vapor or fumes onto XAD-2 sorbent [treated with 2-(hydroxymethyl) piperidine] or charcoal tubes, and then solvent desorption and GC/MS analysis. There have been considerable improvements in air sampling and GC/MS detection.6,7

Another commonly used strategy of GC/MS analysis is the derivative method. Derivatization is an approach for increasing volatility of target analytes which is particularly useful for biological samples. In those cases where compounds are too polar or thermally unstable to be amenable to GC analysis, the situation can be improved by the formation of a suitable derivative with characteristics that render it more amenable to GC. In addition, derivatization can enhance sensitivity and selectivity by altering the fragmentation mechanism of the molecule. A further beneficial effect of derivatization is that it normally results in a compound possessing characteristic ions at mass-to-charge ratios. In tissue analysis, the sample usually requires dialysis after homogenization to remove free monomeric sugars and amino acids. Sample pretreatment of microorganisms for GC/MS analysis generally involves extraction of the class of compounds of interest (e.g. lipids, proteins, or carbohydrates) followed by derivatization.

2.2.2.2 Electron Ionization and Chemical Ionization EI is one of the main ionization methods employed in GC/MS system,8 while CI has also been employed occasionally. In EI, energy sufficient for ionization and fragmentation of the analyte molecules is acquired by interaction with electrons (ca. 70 eV) from a hot filament. Some structural features of the analyte molecule can be deduced from the fragmentation pattern of the molecular ion. During the ionization process, in addition to the production of positive ions, a small number of molecules undergo addition of one or more electrons to form negative ions. At the operating ionizing energy of the analytical mass spectrometer (60–100 eV) the sensitivity of negative ion formation is several orders of magnitude less than that for positive ion production. Compared with EI, CI is a soft ionization technique. It achieves ionization of the analyte by collision with reagent ions (usually proton-rich ions), but without transferring excessive energy to the nascent analyte ions. The result is the formation of abundant adduct ions, often protonated molecules, that contain the intact molecular species of the analyte. In this way, CI and EI are complementary. Because of the soft ionization process, the even-electron molecular adduct ions undergo little fragmentation compared with that of the odd-electron molecular ion produced during EI. Often, CI spectra of individual analytes are sufficiently simple to allow the direct analysis of mixtures, and therefore can be used to provide structural information that is not available from an EI spectrum.

2.2.2.3 Quantitative Analysis and Selected Ion Monitoring The quantitative applications of MS are based on comparison between the ion current obtained from the analyte in the sample matrix and the ion current from another compound chosen as an internal standard, or the ion current obtained from analyses of standard aliquots of the pure analyte. The method of recording the ion current is usually by selected ion monitoring (SIM), although the technique of repetitive scanning over a narrow mass range is sometimes employed. The technique of SIM is one of the most versatile and commonly used spectrometric methods. It allows a mass spectrometer to record simultaneously the intensities of a limited number of chosen ions only. This allows the instrument to dwell for a greater proportion of the analysis time on those mass-to-charge ratios of...
greatest significance in the mass spectrum of the analyte of interest, resulting in an increase in sensitivity. A major application of this technique is to provide quantitative analysis of compounds at low concentrations.\textsuperscript{19}

2.2.3 Applications

In the 1990s, the application of GC/MS and related techniques for the characterization and quantitation of organic compounds and biomarkers has grown spectacularly in environmental health and occupational exposure studies. One such example is the use of GC/MS in the analysis of the health effects of the environmental aromatic hydrocarbons. Polycyclic aromatic hydrocarbons (PAHs) are ubiquitous, and some of them are potentially carcinogenic substances, to which humans are exposed in the environment and in certain workplaces. Estimation of the resulting health risk is therefore of great occupational health importance. The determination of PAHs and their metabolites or protein/DNA adducts as biomarkers is the most suitable way to assess the exposure and to estimate this risk.

Sturaro et al.\textsuperscript{10} have reported a GC/MS investigation of polycyclic aromatic compounds (PACs) in the manufacture of rubber tubes, using a two-stage air sampler and a GC/MS method to monitor eight PACs. With this method, detection limits of 8–15 ng mL\textsuperscript{-1}, corresponding to a level of 12–23 ng m\textsuperscript{-3} in the workplace, were achieved. Workers exposed to airborne aromatic amines in another rubber manufacturing process were evaluated by Menichini et al.\textsuperscript{11} Samples were collected on a glass fiber filter, processed through a silica gel tube, and analyzed by GC/MS/SIM. Their work outlines a procedure for the determination of occupational exposure to airborne aromatic amines in the rubber industry and the application of this method in a tire manufacturing plant. In related work, Menichini et al.\textsuperscript{12} determined PAHs in mineral oils and oil aerosols in glass manufacturing. PAHs were analyzed by GC/MS in graphited mineral oils used for mold lubrication and in aerosols emitted during their application in two plants. High boiling PAHs were detected in oils but generally not in air. Volatile PAHs were found in oil samples and to a lesser extent in air near the emission source. Additionally, Bundt et al.\textsuperscript{13} have investigated structure-type separation of diesel fuels by solid-phase extraction (SPE) and identification of the two- and three-ring aromatics. Commercially available standards were used for identification. Sulfur-containing PAHs in diesel fuel are mainly represented by methyl-substituted dibenzothiophenes. Cooper\textsuperscript{14} has developed a GC/MS method to confirm the presence of N-nitrosamines in workplace air samples. Detection limits of the three procedures and retention time precision of both SIM techniques are good. Typical examples of the use of these techniques for confirmation of N-nitrosamines are described by Cooper.\textsuperscript{14} More applications are summarized in Table 1.

Urinary naphthols (1- and 2-naphthol) have been suggested as route-specific biomarkers for exposure to airborne PAHs.\textsuperscript{27} The application of urinary naphthol levels as biomarkers in 119 Japanese male workers was reported. The urinary 1- and 2-naphthol levels were observed three and sevenfold higher, respectively,

VOCs, volatile organic compounds.
among smokers than among nonsmokers. Also the ratios of urinary 2-naphthol to 1-naphthol were significantly higher among smokers than nonsmokers. In another study, a method for the simultaneous determination of urinary phenanthrene, fluoranthene, pyrene, chrysene and benzo[a]pyrene metabolites has been developed for individual risk assessment at a PAH-burdened workplace.\(^{28}\) The method allows the determination of 25 different components. The PAH exposure of coke plant workers during several consecutive days resulted in fairly constant individual urinary metabolite profiles.\(^{29}\) It was also demonstrated that in the case of coke plant workers there is a correlation between inhaled PAHs and metabolites excreted. Mass relationships between inhaled PAHs and metabolites excreted were found to differ from one individual to another.

The exposures of agricultural workers to organochlorine pesticides were studied by Guardino et al.\(^{30}\) The chlorinated pesticides and their metabolites in whole blood samples from 30 farmers and 24 nonoccupationally exposed workers were determined by GC/MS. The potential that sawmill workers might be exposed to chlorophenols was investigated by Kontsas et al.\(^{31}\) A GC/MS procedure for the determination of chlorophenols in urine was developed. The concentrations of urinary chlorophenols in previously exposed workers were of the same magnitude as those found in nonexposed controls and in the general population. The feasibility of using plasma, blood and hemoglobin (Hb) adducts for monitoring occupational exposure to the suspected human carcinogen 4,4′-methylenebis(2-chloroaniline) (MOCA) was investigated by Vaughan et al.\(^{32}\) The levels of MOCA in the blood and urine of five individuals who were exposed to MOCA during the manufacture were determined by the GC/MS method. It was found that the use of blood samples for monitoring exposure to MOCA offers advantages over the currently used urinary MOCA measurements.

Occupational exposure to toluene diisocyanate (TDI) among workers in a polyurethane foam factory\(^{33}\) was studied during 48-h periods and biological samples from nine subjects. Five workers were found to show high average urinary elimination rates of TDI. The elimination rate curves for all of the subjects studied had a linear relationship with exposure to TDI. The study indicates that it is possible to monitor exposure to TDI by monitoring urinary concentrations of TDI by GC/MS. A study of exposure to benzidine was reported by Hsu et al.\(^{34}\) Exposure to benzidine, which is subsequently acetylated to N-acetylbenzidine and N,N′-diacetylbenzidine, has been implicated in the development of bladder cancer in humans. In this study, an isotope dilution GC/negative ion CI MS method was developed to quantify urine concentrations of benzidine and its acetylated metabolites. The method is applicable to the measurement of other aromatic amines and their acetylated metabolites. Worker exposure to sawing fumes from pine was investigated by Eriksson et al.\(^{35}\) Three metabolites from α-pinenone have been identified in human urine after occupational exposure to it. Urine was enzymatically hydrolyzed, and metabolites were identified by GC/MS using EI and CI with isobutane as the reagent gas. The use of Hb and serum–protein adducts of hazard reagents as biomarkers for occupational and environmental exposure assessment has received increasing interest. The environmental pollutant 2,4,6-trinitrotoluene (TNT) is an important occupational health hazard, and is taken up through the skin and by inhalation. It is therefore essential to have fast and reliable methods to monitor human exposure. In a related work, a GC/MS method, which quantifies Hb adducts of TNT for 50 workers and controls from a Chinese munition factory, was reported by Sabbioni et al.\(^{36}\) The Hb adduct levels ranged from 3.7 to 522 ng. However, in control samples no adducts could be found. In another study,\(^{37}\) alachlor–protein adducts were examined as potential biomarkers of alachlor exposure, a genotoxic and carcinogenic herbicide. The method developed was based on the observation that cleavage of S-cysteinyl alachlor–protein adducts by methanesulfonic acid gave the rearrangement product.

Hb samples from ethylene oxide-exposed workers and nonexposed referents were analyzed by Farmer et al.\(^{38}\) GC/MS was used to determine an Hb adduct as its methyl ester heptfluorobutyl derivative, after hydrolysis of the protein and isolation of the alkylated amino acid. Ranasinghe et al.\(^{39}\) have reported an application of GC/electron capture negative CI high-resolution MS for characterization and quantitation of DNA and protein adducts. The method has adequate sensitivity and specificity to measure accurately DNA and protein adducts as low as endogenous concentrations in rodent and human tissues. Additional applications are listed in Table 2.

### 2.3 Liquid Chromatography/Mass Spectrometry, Liquid Chromatography Tandem Mass Spectrometry and Liquid Chromatography Ion Trap Mass Spectrometry

#### 2.3.1 Principles and Instrumentation

The history of liquid chromatography/mass spectrometry (LC/MS) starts in the early 1970s,\(^{62}\) and since then the technique has been developed rapidly. There are several general reviews\(^{63–66}\) and books published on this subject.\(^{67–70}\) The combination of LC and MS offers the possibility of taking advantage of both LC as a powerful separation technique and MS as a selective and sensitive detector. A considerable number of LC/MS

DDT, 1,1,1-trichloro-2,2-bis[p-chlorophenyl]ethane; MDI, methylenediphenyl diisocyanate; MDA, methylenebisaniline.

Interfacese have been developed. Widely used interfaces included particle beam, thermospray, continuous-flow fast atom bombardment (FAB), electrospray and APCI. Electrospray ionization was one of the most important ionization methods in the 1990s, and is extensively used in LC/MS systems. Electrospray is the result of charging a liquid at a needle tip by applying a high potential. With the increase in the potential, the droplet size is reduced and the droplets begin to have a horizontal component in their movement as well as a higher speed. Nowadays most types of atmospheric pressure ion sources can be used in combination of an electrospray and APCI interface, which is the most widely adapted interface to LC/MS systems.

As a hyphenated technique, LC coupling to MS results in a powerful and versatile analytical tool. Furthermore, LC coupling to a tandem or an ion trap mass spectrometer (LC/MS/MS or LC/MS²) plays another important role in the development of new analytical strategies. MS/MS, generally, includes a collision cell in which deliberate fragmentation of parent ions can be achieved. Collision-induced fragmentation provides daughter ions by collisional energy transfer between parent ions and a collision gas, normally helium, nitrogen or argon, at an elevated pressure. The most widely used MS/MS configuration is the triple quadrupole instrument, where mass analysis is performed in the first and third quadrupole while the second quadrupole is used as a collision cell. It offers a major advantage for structural characterization of components in mixtures and trace analysis. Successful interfacing of this technique has created an effective methodology in the analysis of nonvolatile, labile, and macromolecular compounds. A wide variety of important applications include determination of large portions of protein sequences with either on-line or off-line enzymatic hydrolysis, and development of molecular biomarkers, which represent a more accurate determinant of potential risk of exposure to hazards or carcinogens than those which only assess external exposure.
2.3.2 Methodology

2.3.2.1 Sample Preparation Both on-line and off-line sample pretreatment by SPE are commonly employed in LC/MS, LC/MS/MS, and LC/MS\textsuperscript{g} methods. In quantitative studies of metabolites, and protein–DNA adducts, off-line sample pretreatment appears to be preferred. This is partly due to the composition of biological samples, where the presence of proteins may cause clogging of the SPE columns or cartridges used. For example, a typical Hb and DNA adducts assay involves extraction of DNA or Hb from its biological matrix (e.g., blood or tissue), cleavage of the macromolecule to smaller components, and the use of enrichment techniques, such as derivatization and/or SPE preconcentration. To speed up a complete procedure, the sample pretreatment can be performed on an automated batch-scale SPE. Sometimes, improving the speed and/or performance of the sample pretreatment prior to LC/MS analysis is a matter of considerable research.

After determination of the molecular mass and the elemental composition, the next step in the qualitative analysis is the interpretation of fragment ion peaks in the mass spectrum to achieve structure elucidation. A powerful tool in structure elucidation is the use of MS/MS. The information from a measured spectrum is reduced to a small number of the most significant peaks and then compared with the library spectra. Computerized library searching is very useful as it provides ideas on which direction to search when a completely unknown analyte must be identified, or provides adequate confirmation when the presence of a compound is to be confirmed.

2.3.2.2 Interface Technology In the 1970s, 1980s and 1990s, LC/MS development has resulted in a considerable number of different interfaces. A major effort for this research was to improve the instrument capability to ionize analytes including highly polar, labile and biomacromolecules directly from the liquid phase. The most widely used interfaces are electrospray, APCI, thermospray, particle beam, and continuous-flow FAB. Detailed interfacing strategies are available from a book by Niessen.\textsuperscript{62} The electrospray interface provides one of the most promising interfaces for LC/MS in that it disposes of the mobile phase during spray generation and offers detection limits into the femtomedal range. It has the following advantages: (1) direct ionization from solution; (2) production of multiply charged ions which extend the effective mass range of the mass analyzer; (3) introduction of methods to aid in desolvation of the analyte; and (4) low background from the ionization process. It is remarkable that we can obtain the mass spectrum of a protein with a large molecular mass, and consume an amount of sample of the order of picomoles to femtomoles. APCI is also used for continuous monitoring of an HPLC column. The vaporized eluate from the HPLC is forced through the APCI source with a slow heated stream of nitrogen gas.

2.3.3 Applications

Application of LC/MS in the analysis of workplace and environmental samples has been increasing, especially in the development of exposure indicators. For example, direct analysis of DNA adducts by using LC combined with electrospray ionization MS can obviate those problems arising from the employment of chemical derivatization needed for GC/MS. That is because DNA adducts are usually very polar, and the derivatization is often difficult and less successful. A number of studies have demonstrated that protein–DNA adducts in biological samples can be quantified precisely and accurately by using LC coupling to MS or MS/MS.\textsuperscript{71–75} Workers are occupationally exposed to a wide array of chemical compounds. The compounds or their metabolites can interact with biological macromolecules such as proteins, RNA, and DNA. These interactions can result in covalent bonding between the chemicals and macromolecules, leading to DNA damage and the formation of DNA adducts. If these damages are not enzymatically repaired, they can be the cause of mutations and might lead to chemically induced carcinogenesis. The structural elucidation of these DNA adducts is an important research topic in cancer prevention. The use of DNA adducts as biological markers for risk assessment and occupational and environmental monitoring has generated great interest because they represent direct indications of primary damage to genetic material by chemicals. Therefore, protein–DNA adducts may prove to be more accurate and reliable than measurement of external exposure. To accomplish these goals, a sensitive and specific LC/MS method is capable of detecting low picomole quantities of adduct in relatively small complex biological samples, and is specific enough to confirm the structure of the adducts.

The coupling of LC to MS and MS/MS pertinent to industrial hygiene studies has been reported by a number of researchers. Some of them are summarized in Table 3. In one study,\textsuperscript{76} sensitive and specific isotope dilution LC/MS and LC/MS/MS methods were developed for the detection and quantitation of DNA adducts formed upon exposure of animals to carcinogenic 1,2-dihaloethanes, 1,2-dichloroethane and 1,2-dibromoethane. These are important industrial chemicals used as additives in gasoline, as intermediates in the production of vinyl chloride, vinyl bromide, and other halogenated organics, as components of grain or soil fumigants, and as solvents for cleaners and other industrial products. In another study, an HPLC/electrospray MS method was developed for the analysis of 7-(2-hydroxyethyl)guanine, the major

CP, cyclophosphamide; IF, ifosfamide; MDI, methylenediphenyl diisocyanate.

DNA adduct formed after exposure to ethylene oxide. The method is based on DNA neutral thermal hydrolysis, adduct microconcentration, and final characterization and quantification by HPLC coupled to single-ion monitoring electrospray MS. The method was found to be selective, sensitive, and easy to handle with no need for enzymatic digestion or previous sample derivatization. Yen et al.\(^{77}\) have developed a method to quantify N,3-ethenoguanine, a promutagenic DNA adduct of vinyl chloride exposure. The applicability of the method was established by determining DNA adduct in rats treated with chloroethylene oxide and an unexposed human liver. It was observed that the concentration of DNA adduct in the rat livers increased with increasing dose, but was inversely related to the time after exposure. This trend suggests rapid DNA repair and that adducts reduce in rat livers.

Vanhoutte et al.\(^{78}\) developed a nanoscale LC/electrospray MS methodology for the detection and identification of DNA adducts by in vitro reaction mixture resulting from the interaction of calf thymus DNA with bisphenol A diglycidyl ether. In other work, Singh et al.\(^{79}\) developed an HPLC/electrospray MS method to detect and characterize two major ethylated DNA adducts for monitoring exposure to genotoxic ethylating agents. This approach was shown to be capable of detecting the DNA adduct in liver tissue from mice treated intraperitoneally with N-nitrosodiethylamine. A major chemical in rubber and plastics manufacture, 1,3-butadiene, inducing DNA adducts in vivo and in vitro, was investigated by Tretyakova et al.\(^{80}\) The LC/electrospray MS/MS methods developed in this work provide the means to study accumulation, repair and dose–response relationships of 1,3-butadiene–DNA adducts in vivo.

Occupational exposure to cyclophosphamide (CP) and ifosfamide (IF) was investigated by Minoia et al.\(^{81}\) An LC/MS/MS system was employed to monitor CP and IF exposure of 24 workers. The extent of exposure was assessed by the analysis of air samples, wipe samples, dermal pads, and urinary excretion at the beginning and at the end of the work shift. The results of this investigation demonstrate that higher risk may be caused by incorrectly using airflow hoods.

Benzene is an important industrial chemical and ubiquitous environmental pollutant. It is used in the manufacturing of a wide variety of consumer products. Melikian et al.\(^{82}\) developed a sensitive and specific LC/MS/MS assay for determination of urinary benzene metabolites. The objective of this study was to investigate how various levels of exposure affect the metabolic activation pathways of benzene in humans and to examine the relationship between urinary metabolites and other biological markers. Ferranti et al.\(^{83}\) used LC/MS/MS for the structural study of adducts formed in human Hb by in vitro exposure of erythrocytes to the alkylating agent methyl bromide (MeBr). MeBr is a highly toxic gas widely used as a fumigant of field soil for control of a wide spectrum of pests and diseases. Peptide mapping by this method allowed location of methylated amino acids within the protein sequence. The results demonstrated the usefulness of the analytical approach for the characterization of Hb adducts with methyl bromide or similar compounds, which can constitute the basis for biomonitoring of human exposure.

The LC/MS, LC/MS/MS, or LC/MSn techniques have been developed for characterization and quantitation of pesticides, herbicides, and insecticides.\(^{84}\) For example,
2.4 Inductively Coupled Plasma Mass Spectrometry

2.4.1 Principles and Instrumentation
The inductively coupled plasma (ICP) was first utilized as an ion source for analytical MS by Montaser. The degree of ionization of most elements is 90% or greater. Since its introduction, ICPMS has exhibited a large number of special attributes. The most important and unique characteristics of the argon ICP are as a viable source for simultaneous multielement analysis with high sensitivity. In ICPMS, the test sample is typically converted to an aerosol and transported into the plasma where the desolvation-vaporization-atomicization-excitation-ionization processes occur. In comparison with classical combustion flames, the argon ICP exhibits a high gas temperature (4500–8000 K) and a high electron temperature (9800–10 000 K). Such conditions coupled with the relatively long plasma–sample interaction times lead to nearly complete vaporization-atomization of sample aerosol, and also reduce the chemical and physical interferences in the plasma.

In general the ICP source coupled with a quadrupole MS allows a multiple-elemental, multiple-isotope analysis to be performed. Increasingly, the argon ICPMS is replacing established atomic emission and atomic absorption spectrometries for trace or ultratrace element research. ICPMS offers simultaneous or rapid sequential multielement determination capability at major, minor, trace, and ultratrace concentration levels. Indeed, it is the most powerful means for determination of trace inorganic metals.

2.4.2 Methodology

2.4.2.1 Sample Preparation The sample preparation for ICPMS measurement is not substantially different from that encountered in other atomic spectrometric methods. Dissolution of a heterogeneous sample which provides homogeneity at the molecular level is usually required. Elemental analysis can be performed in nearly all kinds of matrices. The development of sample decomposition for ICPMS is an important step in sample preparation. It relies on sample type, specific analyte species of interest, and analyte molecular interactions. Most biological samples are prepared by decomposing the sample using thermal or chemical means, followed by dissolution of the ash residue and dilution to a specific volume prior to analysis. Microwave digestion is often used. Another common technique is a hot-plate dissolution procedure, but there are several primary limitations, such as long dissolution times and the potential loss of volatile elements. In a microwave digestion technique, closed vessels are utilized to decompose samples and minimize loss of volatile elements during the digestion process. During sample preparation, the elements being determined, their analysis requirements, and specific interferences that might be encountered for their determination dictate whether separation and preconcentration steps might be required. Sometimes, sample preparation may be a lengthy and complex process, depending on the form of the sample and the specific elements being determined.

2.4.2.2 Quantitative Analysis Quantitative analysis by ICPMS can be achieved by the use of a precise peak-hopping/signal integration procedure. Two modes of operation typically are used: rapid spectral scanning and peak hopping. The most commonly used mode, the rapid scanning method, covers the entire mass range. By closely matching the bulk chemical composition of the calibration standards to the known matrix of the samples, improved accuracy can be obtained. The use of internal standards is highly recommended to achieve maximum precision and accuracy. The calibration curves for selected elements, when plotted on logarithmic axes, demonstrate linearity over a wide dynamic range. Most modern ICPMS instruments offer a wide dynamic range. The ICPMS technique also provides sufficient isotope ratio precision and sensitivity to enable isotope dilution quantitation at trace concentration levels. Additionally, flow injection analysis (FIA) has been successfully used to improve the quantitative determination of trace elements in samples with high dissolved solids. Chemical modification of the sample can be performed by the addition of reagents to the transport line. Another significant advantage of the flow injection technique is the ability to make measurements on microsized samples, especially when high efficiency nebulizers are used.

2.4.2.3 Laser Ablation Laser ablation was first reported for sample introduction into ICPMS by Gray. With this method, samples can be analyzed with minimal sample preparation. Usually specimens of metal alloys or similar materials are prepared by grinding or polishing a flat surface. Similar to other solid sampling techniques, it provides viable analytical results when suitable solid standards are available. Laser ablation ICPMS also gives important spatial resolution, which is particularly useful for the determination of the chemical composition.
of grain boundaries or mineral inclusions. It is a very powerful method for the analysis of particulates or solid samples.

2.4.3 Applications

ICPMS has been utilized effectively in industrial work environments. It has been effectively used for trace analysis with high sensitivity, especially for the traditionally “difficult-to-excite” refractory elements such as molybdenum (Mo), vanadium (V) and zirconium (Zr), and with multielement detection capability. The applications include the determination of trace elements in air, exhaust, liquid, and dust in various working environments. Monitoring occupational exposure to heavy metals with the ICPMS technique had been reported by several researchers, although atomic absorption spectrometry has until now been used most extensively in occupational and environmental health. In one study, Schramel et al. established an ICPMS analytical method to determine the concentration of antimony (Sb), bismuth (Bi), lead (Pb), cadmium (Cd), mercury (Hg), palladium (Pd), platinum (Pt), tellurium (Te), tin (Sn), thallium (Tl) and tungsten (W) in urine. The aim of this work was to develop a method which is equally suitable for the determination of occupationally as well as environmentally caused metal excretion. In another study, Apostoli et al. evaluated multiple exposure to metals in eight types of metal welding, such as manual metal arc for mild and stainless steel, continuous wire, submerged arc, and brazing. Environmental monitoring was carried out in eight different occupational situations and the ICPMS technique was adopted in order to characterize exposure to several elements simultaneously and with high accuracy. The results showed that up to 23 elements could be measured. The highest concentration was found for aluminum (Al), manganese (Mn), iron (Fe), nickel (Ni), chromium (Cr), copper (Cu) and zinc (Zn). Karpas et al. presented a simple method, based on ICPMS, for determination of uranium in urine at levels that indicate occupational exposure. Sample preparation involves a 50-fold dilution of the urine by nitric acid (2% HNO₃) and no other chemical treatment or separation. The analytical procedure is fully automated so that over 100 analyses may be performed per day. Measurement by ICPMS of lead in plasma and whole blood of lead workers and controls was reported by Schutz et al. The levels of lead in blood plasma and whole blood were measured by ICPMS in 43 male lead smelter workers and seven controls. The samples were handled under routine laboratory conditions. By a simple dilution procedure, lead in plasma may be determined accurately and with good precision down to the concentrations present in controls. It suggested that lead in blood plasma should be considered as a complement to current indicators of lead exposure and risk. Application of ICPMS to monitor radionuclide was reported by Vita and Mayfield. An ICPMS method was developed to detect U-235 and U-238 in urine. The strong nitric and hydrochloric acid digestion of the urine and the application of the anion exchange resin for the uranium separation provided dependable recovery. In addition, multiple exposure to arsenic (As), antimony (Sb), and other elements in art glass manufacture was studied by Apostoli et al. The results confirmed that arsenic, which is the main hazard in glass production, reaches a high air concentration.

2.5 Time-of-flight Mass Spectrometry, Fourier Transform Ion Cyclotron Resonance Mass Spectrometry and Future Trends

2.5.1 Introduction

TOFMS was introduced commercially in the late 1950s. However, it was only in the 1990s that the high mass range and the high sensitivity multichannel recording capabilities were realized, which make this type of spectrometry an attractive instrument for contemporary research. A typical TOFMS system contains three main components: ion source, ion drift region, and detection system. A new generation of high-performance TOFMS instrumentation includes nanoflow electrospray hybrid quadrupole TOFMS and MALDI/TOFMS. Modern TOF instruments have many intrinsic advantages. They are ideally suited for pulsed ion sources because they have a sufficiently narrow pulse width, and a fast response. They can provide macromolecular measurements of proteins with considerably higher accuracy than gel electrophoresis, or can be used to map enzymatic digests, reveal post-translational modifications, determine the positions of disulfide bonds, assess carbohydrate heterogeneity in glycopeptides, or provide amino acid sequences.

FTICRMS is now an established viable analytical technique. FTICRMS allows in principle an unlimited mass range to be reached with an extremely high resolution. As a technique based on Fourier transform, the resolution depends on the observation time, which is linked to the disappearance of the detected signal. In order to achieve high resolution, a very high cell vacuum is necessary, which is a major limitation of this technique. The advancing technologies of hybrid QTOFMS, MALDI/TOFMS and FTICRMS are just beginning to add much needed analytical power to our arsenal for macromolecular identification and characterization. An application of more efficient collision-induced dissociation and product-ion detection is using a hybrid of quadrupole and TOF analyses in QTOFMS. These developments will bring important methodology to scientists and thus accelerate the integration of MS into
work-related research strategies. Research will include structural determination of aberrant proteins, development of biomarkers for specific hazard to exposed workers, characterization of protein allergens related to occupational asthma, and identification of microbial products in complex environmental samples.

2.5.2 Matrix-assisted Laser Desorption/Ionization Time-of-flight Mass Spectrometry

A rapidly advancing area in which TOFMS plays a major role is in MALDI/TOFMS. It has developed into a powerful tool for characterizing biological macromolecules. In a MALDI/TOFMS experiment, the analyte of interest is mixed with an appropriate matrix material which facilitates the desorption and ionization of intact analyte molecules with masses up to several hundred thousand m/z. This absorbs strongly at the wavelength of the incident laser light. Many very large biomolecules have been mass analyzed by this technique. MALDI/TOFMS is able accurately to sequence single strands from DNA without the need for labels or primers, and to identify single base mutations within a polymerase chain reaction (PCR) product. Although the effective range of sequencing may not be as wide as with conventional methods, MALDI/TOFMS can sequence short DNA strands in less time with the ability to identify all of the bases in the strand. Single strands and PCR products of up to 500 bases have also been detected, but it is not clear whether the mass accuracy and resolution will be sufficient for sequencing long strands. Peptide mapping by MALDI/TOFMS is gradually reaching a confidence level owing to improved mass accuracy and sample preparation methods and the availability of complete genomic information for a number of organisms.

MALDI/TOFMS has been applied and established as a valuable analytical technique for the detection of PAHs with high spatial resolution in the work environment. Bezabeh et al. investigated nitrated PAH pollutants generated by incomplete combustion using negative ion laser desorption ionization TOFMS. In related work, spatially resolved laser desorption/laser ionization TOFMS has been used for the detection of PAH–picrate complexes, and PAHs in individual micrometer-sized diesel particulate.

2.5.3 Hybrid Quadrupole Time-of-flight Mass Spectrometry

The development of a hybrid QTOFMS instrument overcomes the mass range and precursor ion resolution limitations of a triple-quadrupole mass spectrometer. A particular advantage that this hybrid has over the triple-quadrupole instrument is that it can provide high precursor ion resolution by virtue of its double focusing properties and it may be used to obtain MS/MS information from precursor ions of the same nominal mass. The sequencing of larger proteins by enzymatic cleavage and subsequent MS/MS analysis of the resulting peptides by QTOFMS is well documented. With the advantage of electrospray, also enabling an on-line nanoflow LC coupling to QTOFMS, this approach has found a few applications. For example, Deforce et al. characterize DNA oligonucleotides by coupling of capillary zone electrophoresis to electrospray ionization QTOFMS. A procedure for fast and precise molecular weight, purity, and base composition determination of oligonucleotides was described. This method has been useful not only for determination of the purity and the length of bases in oligonucleotides, but also for confirmation of the expected base composition, making this technique an extremely useful tool for quality control in the field of oligonucleotide research. Hybrid QTOFMS has just started to be applied to occupational health studies.

3 SCANNING ELECTRON MICROSCOPY AND X-RAY MICROANALYSIS

3.1 Introduction

The scanning electron microscope, when equipped with an EDX analysis system and an IA, is ideally suited to study pneumoconioses and workplace environmental particles. The salient features of this instrumentation which make it valuable in occupational safety and health applications are discussed very briefly below. For a comprehensive description of the instrumentation and theory, the reader is referred to the texts by Goldstein et al. and Lee. An excellent short description of SEM and X-ray analysis principles and instrumentation is given by Ingram et al.

3.1.1 Instrumentation

In SEM, a focused beam of electrons is scanned in a raster pattern across a specimen of interest. Numerous complex events occur at each point where the electron beam impinges on the atoms of the specimen. Some, but by no means all, of the signals produced by the electron beam–specimen interaction are illustrated in Figure 1.

By utilizing an appropriate detector for a specific signal, an image of the specimen can be constructed on a point by point basis. For instance, the detection of secondary electrons, which are very low energy electrons arising from very near the surface of the specimen, is used to produce the secondary electron image (SEI). The SEI is the three-dimensional-like image
Some signals resulting from the interaction of the electron beam with a specimen.

Figure 1

Some signals resulting from the interaction of the electron beam with a specimen.

Figure 2 BEI of a 5-µm thick section of lung tissue from a subject with silicosis showing numerous particles (brighter areas). Marker = 10µm.

Another extremely valuable attachment for SEM is an IA. A computer-based IA permits rapid, real-time automated characterization of SEM image features, including size measurements and chemical analyses when used in conjunction with an EDS. The system currently used in our laboratory is PC-based (personal computers) and controls the scanning of the electron beam across the specimen. A regular grid point spacing pattern is used with a preset point density to locate features. At each point, the image signal (we use the backscattered electron signal) is compared to an adjustable threshold to determine whether the beam is on a feature of interest. Once a feature is found, a narrower grid point spacing pattern is used to determine physical parameters, and subsequently an X-ray analysis of the feature is performed. For more information on IAs, the reader is referred to the review paper by Lee and Kelley,110 and the text by Friel.109

Characteristic X-rays result from the ejection of inner shell electrons of the specimen atoms by the electron beam. The generation of characteristic X-rays forms the basis for chemical analysis of the specimen since both the wavelength and the energy of the characteristic X-rays can provide definitive information about the atoms from which they emanate. In SEM, X-rays may be measured through the use of either a wavelength dispersive spectrometer (WDS) or an energy dispersive spectrometer (EDS). With the WDS, the wavelengths of X-rays are determined using crystal diffraction and Bragg’s law. The EDS detects the energies of X-rays using a lithium-drifted Si crystal. The WDS has better spectral resolution compared with the EDS, and is capable of light element detection. However, only one element at a time can be determined with a WDS. The characteristic peaks of all elements with an atomic number of 9 (fluorine) or greater can be detected simultaneously with the standard EDS. Light element detection is also possible with EDS systems that have windowless detectors or detectors with ultrathin windows. The texts by Goldstein et al.,105 Lee,106 Heinrich,108 and Friel109 contain extensive discussions of X-ray analysis and instrumentation.
SEM and EDX analysis may be used for a number of applications in occupational safety and health including the analysis of particles collected on air filter samples taken from the working environment, analysis of individual particles found in bulk dusts, and in the study of pneumoconioses. Applications of SEM to the study of pneumoconioses, including determination of lung particulate burden, particle chemistry, and respirable particle surface characterization, will be described in the subsequent sections.

3.2 Sample Preparation

There are two ways to study particles found in lung tissue. One examines the particles in situ, i.e. particles may be located by SEM (usually using the BEI) and an EDX analysis performed while the particles are still in the tissue. An alternative procedure is to extract the particles from the tissue matrix followed by EDX analysis. Sample preparation procedures and the advantages and disadvantages of these two techniques are described briefly below. A complete discussion of SEM preparation techniques is given by Shelburne et al.\textsuperscript{111} The paper by DeNee\textsuperscript{112} also describes various preparation techniques.

3.2.1 Tissue Preparation for In Situ Particle Analysis

The key advantage of SEM in situ analysis in the study of pneumoconioses is the opportunity to correlate the location, types, and concentration of particles found with any tissue pathology seen by light microscopy. On the other hand, in situ analysis is very time-consuming because particles must be identified and analyzed manually. The preparation of lung (or other types of) tissue for light microscopic and SEM examination generally involves formalin fixation, followed by paraffin embedding. Serial sections (5-µm thick) are cut from the paraffin block both for light microscopy and SEM analysis. The sections for SEM are mounted on a carbon substrate (we use 1-inch, or 2.5-cm, diameter carbon planchets), de-paraffinized using xylene, and air dried. The final specimens generally do not need coating for conductivity. However, if specimen charging is a problem, the specimen may be coated with carbon using a vacuum evaporator. Metal coatings should be avoided because they may interfere with subsequent EDX analyses. As can be seen in Figure 2, particles are easily located in the 5-µm section; however, they may occur in aggregates, making individual particle analyses a challenge.

3.2.2 Tissue Particle Isolation Techniques

The key advantage of isolating particles from the tissue matrix is the speed with which subsequent analyses may be performed. Once the tissue matrix is removed, a filter containing the residual particles may be prepared, and the particles analyzed using an automated SEM/EDX/IA procedure. The analysis procedure used in our laboratory is described in the paper by Thomas and Hollahan.\textsuperscript{113} The procedure we use for lung tissue consists of the following steps: 1–2 g of fresh tissue is selected and diced into 1–2-mm cubes, and freeze dried to constant weight. Approximately 0.1–0.2 g of the dry tissue is accurately weighed, placed in a clean glass vial, and ashed in a low-temperature asher at 90 W for 7 h at an oxygen pressure of 2 Torr. The ash is suspended in 50 mL of a solution of 0.05% Aerosol OT\textsuperscript{®} in filtered, deionized water, and then placed in an ultrasonic bath for 15 min. One milliliter of glacial acetic acid is added to the suspension which is then made up to a final volume of 100 mL with filtered, deionized water and allowed to stand overnight. Since the particulate burdens of lungs vary considerably, preparation of samples with the proper particle loading for automated analysis is accomplished by filtering varying aliquots of the final suspension onto 25-mm diameter, 0.1-µm pore size polycarbonate (Nuclepore\textsuperscript{®}) filters. The filters are attached to carbon planchettes with colloidal graphite, and may be examined uncoated under SEM. Filters with proper loading have minimal particle overlap and generally contain approximately 50–100 particles per field of view at a magnification of 1000X. It should be noted that some particles present originally as aggregates in the tissue may not be broken apart during the low-temperature ashing procedure.\textsuperscript{114}

3.2.2.1 Low-temperature Ashing

In the low-temperature ashing process, an oxygen plasma is used to oxidize the organic components of the tissue matrix. A review of the application of low-temperature ashing in preparing samples for SEM analysis is given by Thomas and Hollahan.\textsuperscript{113} The procedure we use for lung tissue consists of the following steps: 1–2 g of fresh tissue is selected and diced into 1–2-mm cubes, and freeze dried to constant weight. Approximately 0.1–0.2 g of the dry tissue is accurately weighed, placed in a clean glass vial, and ashed in a low-temperature asher at 90 W for 7 h at an oxygen pressure of 2 Torr. The ash is suspended in 50 mL of a solution of 0.05% Aerosol OT\textsuperscript{®} in filtered, deionized water, and then placed in an ultrasonic bath for 15 min. One milliliter of glacial acetic acid is added to the suspension which is then made up to a final volume of 100 mL with filtered, deionized water and allowed to stand overnight. Since the particulate burdens of lungs vary considerably, preparation of samples with the proper particle loading for automated analysis is accomplished by filtering varying aliquots of the final suspension onto 25-mm diameter, 0.1-µm pore size polycarbonate (Nuclepore\textsuperscript{®}) filters. The filters are attached to carbon planchettes with colloidal graphite, and may be examined uncoated under SEM. Filters with proper loading have minimal particle overlap and generally contain approximately 50–100 particles per field of view at a magnification of 1000X. It should be noted that some particles present originally as aggregates in the tissue may not be broken apart during the low-temperature ashing procedure.\textsuperscript{114}

3.2.2.2 Chemical Digestion

Biological tissues may be chemically digested using a number of different agents including oxidizing agents (sodium hypochlorite), strong alkaline solutions (sodium or potassium hydroxide), and proteolytic enzymes (ficol). Digestion with each of these agents is reviewed briefly in the paper by Mastin et al.\textsuperscript{115} In our laboratory, we have used an adaptation of the sodium hypochlorite digestion procedure described by
Coin et al.\textsuperscript{(116)} to prepare lung tissue for particle analysis. Approximately 0.1–0.5 g of wet, formalin-fixed tissue is accurately weighed and placed in a clean glass vial. A second piece of wet tissue is also weighed and then dried to constant weight to determine the wet-to-dry weight ratio. Ten milliliters of triple-filtered sodium hypochlorite are added to the glass vial containing the wet tissue, and the vial is then shaken gently for 30–45 min. The digestate is filtered onto a 0.2-µm pore size polycarbonate filter and washed with 10 mL of deionized water. Lipids and other undigested debris are then extracted from the filtrate by two treatments with the following sequence of triple-filtered reagents: 10 mL of isopropanol, 10 mL of 7% oxalic acid, 10 mL of Clorox\textsuperscript{®}, and 10 mL of deionized water. The filter may now be dried and processed as before for SEM analysis. We have found that this digestion procedure takes less time to prepare samples than low-temperatureashing. There are a couple of negatives, however. The washing steps may lead to an uneven redistribution of the particles on the filter. In addition, achieving the proper particle loading on the filter may require some experimentation with the initial sample wet weight or separation of the initial digestate into aliquots of varying volumes.

3.3 Lung Particle Analysis

Particulate matter has been recognized as a cause of various lung diseases, the pneumoconioses, for many years. Specific pneumoconioses such as coalworker’s pneumoconiosis, asbestosis, and silicosis may result from inhalation of particles at the worksite. Numerous methods, as reviewed by Mastin et al.\textsuperscript{(115)} have been used to analyze particulate matter deposited in human lungs. SEM and EDX have been used extensively to characterize particles found in lung tissue (see reviews by Shelburne et al.\textsuperscript{(111)} and Baker et al.\textsuperscript{(117)}). While it is not possible to compare a measured lung dust burden to the actual exposure because of the lack of exposure data and to particle clearance, the measured lung particulate burden does represent retained particle dose. Everyone has a background lung particulate burden resulting from inhalation of respirable particles present in the ambient environment. Hence, a good database for the particle contents of the lungs of subjects with no pneumoconioses and/or history of occupational exposures, i.e., “normal” lungs, is needed so that the particle analysis data from diseased lungs can be properly interpreted. The application of SEM and EDX to the determination of inorganic particulate burdens for normal and diseased lungs, as well as respirable particle surface characterization, will be discussed in the next sections.

3.3.1 Normal Lung Inorganic Particulate Burdens

We have used an automated SEM/EDX/IA method to determine the lung nonfibrous, inorganic particulate burdens for a large set of subjects with no overt pneumoconioses. This procedure is not suitable for fiber analyses because mineral fibers usually have very small diameters and do not produce a BEI with enough contrast for automated analysis. In addition, organic particles, such as coal, are destroyed in the low-temperature ashing process. Complete details of the automated method for nonfibrous particles are given in the paper by Stettler et al.\textsuperscript{(118)} Briefly, a small portion of freeze-dried lung homogenate from each subject was ashed in a low-temperature asher and filters containing the residue prepared as described earlier in this report. The filter samples were analyzed in the electron microscope which was equipped with an EDS and an IA using the BEI image. After a field of view is selected, particles in the field are automatically detected by the IA, sized, and then analyzed for 31 elements using an X-ray spectrum acquire time of 5 s. In our procedure, a minimum of 1000 exogenous particles in a minimum of 20 randomly selected fields of view at a magnification of 1000X are analyzed. The IA grid point spacing density used in the procedure is set to find particles 0.2 µm in diameter and larger. After X-ray analysis, the particles are classified by the IA using a chemistry definition file which defines particle types by their major elemental components and net fractional X-ray intensities. The list of elements analyzed and a description of the chemistry definition file are given in the book chapter by Stettler et al.\textsuperscript{(119)} More than 145 000 individual particles were analyzed in this study. The average (±standard deviation) exogenous particle concentration found in 87 lungs was 476 ± 380 × 10\textsuperscript{6} particles per gram (ppg) of dry lung with a range of 71–1860 × 10\textsuperscript{6} ppg. On average, various aluminum silicates accounted for 38.1% and particles classified as silica accounted for 21.0% of the particles in the 87 lungs. Large numbers of various metal-containing particles, primarily titanium and iron occurring singly or in combination with Si, were also found in the lungs. The particle levels seen in the study by Stettler et al.\textsuperscript{(119)} were similar to those seen in other studies of normal lungs by Churg and Wiggs\textsuperscript{(120,121)} and by Paolelli et al.\textsuperscript{(122)} Analytical transmission electron microscopy methods were used in the other studies with average particle concentrations in the range 180–465 × 10\textsuperscript{6} ppg.

3.3.2 Inorganic Particulate Burdens of Lungs with Pneumoconioses

Although the automated SEM/EDX/IA method described above has been used to determine the particulate burdens in lungs with suspected occupational exposures
by Stettler et al.,\textsuperscript{(114)} many studies have involved manual in situ analyses using 5-µm thick sections of lung tissue. Of particular note is the work of Abraham et al.,\textsuperscript{(123–125)} who have developed and used an in situ procedure to determine the nonfibrous, inorganic particulate burdens of over 400 lungs. Their procedure uses 5-µm thick sections mounted on carbon. Complete descriptions of their SEM analysis procedure are given elsewhere.\textsuperscript{(124,125)} Briefly, a morphometric point counting approach using both the SEI and BEI at a magnification of 6000X is used to locate particles in randomly selected fields. The number of particles in 100 consecutive fields are counted. If fewer than 100 particles are counted, additional fields are analyzed. The particles are sized and analyzed using a 20-s X-ray analysis. Size and elemental data in the form of net X-ray counts per second for each element observed are recorded. EDX data are used to sort exogenous particles into three major classes: silica (showing only a silicon peak), silicates (showing silicon and other cations such as Al, Mg, K, Ca, Fe), and other (mostly metals, either singly or in combinations). Particle concentration data are reported in terms of particles per cubic centimeter. The average total exogenous particle concentration for 433 cases by this technique was 473 ± 113 × 10⁶ particles cm⁻³ with concentrations in the range 1–33 450 × 10⁶ particles cm⁻³.\textsuperscript{(123)} The major types of particles found included silica, aluminum silicates, metals, and talc.

### 3.3.3 Respirable Particle Surface Characterization

Bulk compositional analyses of respirable particulate material, and even particle-by-particle compositional analyses, may not always be sufficient to predict the level of biological activity of respirable particles or the health risks of exposure to them. Toxicants may be located on the particle surface or may be more heavily concentrated there, resulting in heightened biological availability and expression of toxic activity. Or, in some cases, surface coating materials may have a prophylactic effect on expression of the toxicity of the underlying bulk of the particle. An example of the latter effect is the modified activity of the quartz component of some mixed composition mineral dust exposures for causing mixed dust pneumoconioses by LeBouffant et al.,\textsuperscript{(120)} Kriegseis and Scharmann,\textsuperscript{(127)} and Harrison et al.\textsuperscript{(128)}

#### 3.3.3.1 Multiple-voltage Scanning Electron Microscopy with X-ray Spectroscopy: Experimental SEM with EDS or WDS X-ray spectroscopy can provide some information on the elemental composition with depth into a particle, by acquiring X-ray spectra at two or more electron beam accelerating voltages.\textsuperscript{(129)} The depth of penetration of electrons and of the excitation of characteristic X-rays is dependent on the incident electron energy and on the density of the particle target. For densities in the range of most respirable particulate minerals, a 20–30keV electron beam will excite spectra to a depth of the order of one to a few micrometers. This range is a function of electron voltage such that a 5-keV electron will excite spectra to a depth of the order of 0.1–0.01 µm in such materials. Thus, comparing spectra acquired at 20keV and at 5keV can provide some indication of the homogeneity or heterogeneity of elemental distribution with depth into a particle. This method has been used to detect thin submicrometer aluminosilicate coatings or clay “surface occlusion” on respirable quartz particles.\textsuperscript{(130)} To control for correction factors, comparison is not made of the absolute values of elemental spectral line intensities; instead, the ratio of spectral line intensities of different elements in a particle is measured at one voltage and compared with the ratio measured at another excitation voltage. For example, the ratio of the silicon line intensity to the aluminum line intensity of a particle is measured at 20-keV excitation and then is measured at 5-keV excitation, or is measured at a series of voltages, e.g. 20, 11, 9, 7, 5 keV. The beam generally must be relocated on the particle of interest after a voltage change. This can be done in an automated mode with modern SEM/EDS computer-controlled systems. Using such systems, several fields of particles can be analyzed for several hundreds of particles at one voltage, and the same fields can be reanalyzed at a second voltage. Typically, some smaller particles identified at one voltage in computer-controlled data acquisition will be missed at the other voltage. But visual editing of the resultant files can easily assure proper matching of particles for comparison of the ratio of elemental line intensities between the two voltages. Obviously, the electron beam voltage must be greater than the energy (frequency) of the X-ray lines used in the analysis. This can be a problem for analyses at the low electron beam accelerating voltages: 5-keV electrons will not excite the K series lines for heavier elements. In some cases this can be circumvented by using the higher series lines (L, M, . . .) which occur below 2 keV.

#### 3.3.3.2 Multiple-voltage Scanning Electron Microscopy with X-ray Spectroscopy: Interpretation Change in measured spectral line intensity ratios versus electron beam accelerating voltage can be predicted as a function of particle density and size with an analytical formula.\textsuperscript{(130)} Diminution of the electron beam intensity with depth of penetration into a material can be modeled in one dimension as a Beer’s law process, i.e. differential loss of intensity is proportional to intensity in a differential thickness of material.\textsuperscript{(131)} Empirical relationships are available for this proportionality constant as a function...
of electron voltage. In the differential thickness of material the electron beam will stimulate characteristic X-rays. An X-ray line intensity is a function of the intensity of the electron beam with adequate energy to stimulate the given X-ray line, of the concentration of target atoms, of the cross-section for ionization of the target atom shell by those electrons, and of the fluorescence yield or probability that the electron-excited atom will decay by the specific X-ray emission. A simple empirically determined function provides a model for the effective scattering ionization cross-section versus incident electron energy and X-ray spectral line frequency. Tabulated values of fluorescence yield are available. These together can be used to describe the generation of X-rays with depth by the electron beam. Then a Beer's law model can describe extinction of the generated X-ray as it leaves the particle. Together these models of electron stimulation of X-rays and of X-ray emission provide a differential equation for X-ray line intensity as a function of material thickness, material density, electron beam voltage, X-ray spectral line frequency, and fluorescence yields. This differential equation can be solved across the particle boundaries for alternative models of particle structure with depth, e.g. for a homogeneous mixed composition particle versus a heterogeneously structured particle. This provides a prediction of the change in measured elemental composition ratios versus electron beam accelerating voltage. These predictions then can be used to interpret measurements of X-ray elemental spectral line intensity ratios of a particle versus electron beam accelerating voltage in terms of particle compositional structure with depth. An example in the literature details application of the model to aluminosilicate-contaminated silica particles. Predictive models for a silica particle homogeneously contaminated with aluminum and for a silica core particle with an aluminosilicate clay coating were compared with experimental data of silicon to aluminum line intensity ratios measured at 20–5-keV electron beam accelerating voltages. As an example of “occluded” particle behavior, for a 2-µm thick particle of 97% Si/(Si + Al) overall composition, the measured fraction of silicon drops to below 80% at 5 keV, in concert with the prediction for a clay-coated particle.

3.3.3.3 Scanning Electron Microscopy with Scanning Auger Spectroscopy for Particle Surface Analyses

Scanning Auger spectroscopy uses electron imaging and excitation of particulate samples much as SEM does. However, electron-excited emission of Auger electrons rather than characteristic X-rays provides the mechanism for elemental analysis. The shallow escape depth of these Auger electrons results in information being obtained only from the depth of a few atomic layers into the sample. This provides a very near surface analysis compared to that provided by SEM/EDS, essentially measuring elemental composition in a nanometer thickness compared to a micrometer thickness. Scanning Auger spectroscopy also provides a more shallow depth of analysis by one to two orders of magnitude than is reasonably achievable by multiple-voltage SEM/EDS, that is, 1 nm depth by Auger versus 10–100 nm minimum depth by multiple-voltage SEM/EDS. To some extent, sample preparation and purity constraints are alleviated in the multiple-voltage SEM method: incidental surface contamination on samples may need to be removed prior to Auger analysis by argon ion bombardment of the sample. For analysis of particles in lung tissue thin sections, scanning Auger spectroscopy is not appropriate, while multiple-voltage SEM/EDS can provide some identification of surface occluded mineral particles in 5-µm thick tissue sections. For dust samples, a combination of conventional (20–30-keV) SEM/EDS, of multiple-voltage SEM/EDS, and of scanning Auger spectroscopy provides the possibility of analyzing respirable particle samples for elemental composition from their bulk to their surface. Performing these joint analyses on explicit particles is challenging but possible. Modern automated methods provide the capability for performance of that suite of analyses on a large population of respirable-sized particles with the same specific particles analyzed in all three regimens. This has been demonstrated for the combination of SEM/EDS and scanning Auger spectroscopy for cobalt, chromium, and tungsten analyses of respirable hard metal particles.

4 ATOMIC SPECTROMETRY

4.1 Introduction

Atomic spectrometric techniques are the most widely used analytical techniques for quantitative analysis of inorganic metals. The techniques have been applicable to nearly all the elements, including most of the metals and semimetals. The development of ICPAES techniques has been increasing. ICPAES offers a simultaneous or rapid sequential multielement determination capability at the major, minor, and certain trace concentration levels. It has become established as a widely accepted method for the analysis of metallic aerosols, powders of metals, dusts, and fly ashes. To date, a vast number of published atomic spectrometric methods are available, covering a wide range of applications. Atomic spectrometric methods are widely employed for occupational health evaluation, owing to the presence of trace elements in the atmosphere released from various industrial processes.
4.2 Flame Atomic Absorption Spectrometry

4.2.1 Principles and Instrumentation

Flame atomic absorption spectrometry (FAAS) has been used for the determination of about 65 elements with detection limits ranging from a few parts per billion to a few parts per million. Instruments are reliable, robust and simple to use. It is a single channel instrument, but operating conditions can be changed rapidly so that several elements can be determined in one sample in an automated sequential run. Two types of flame mixtures are commonly used: air–acetylene and nitrous oxide–acetylene. The latter flame is significantly hotter and is needed to atomize some elements such as aluminum, which form refractory oxides. The sample solution is pneumatically nebulized into a spray chamber where a sample mist is formed and mixed with a fuel gas. Then, the sample aerosol enters a flame where dissociation and atomization occur. During the rather limited residence time in the flame, the droplets are dried and the resulting salt particles vaporized. The resulting molecular species may be atomized by thermolysis or by chemical reaction with reducing species such as carbon and carbon monoxide. Generally, FAAS is selective, rapid, and amenable to automation with adequate sensitivity.

4.2.2 Methodology

4.2.2.1 Sample Preparation

In a typical FAAS assay, an analyte is dissolved into a solution. The sample preparation procedure depends strongly on the properties of both the target elements and the solvent matrices. The principal objective of sample preparation is to dissolve target analytes, and to remove interferences. The method of liquid–liquid extraction is a convenient way of preparing some samples in which the target analytes are easily dissolved in the solution. It is relatively simple, rapid, and favorable to FAAS. Organic solvent can also be used to enhance detection sensitivity. Methyl isobutyl ketone is the most popular solvent because of its extraction and nebulization efficiency as well as combustibility. Other solvents such as ketones or esters can be used as well. In the pulse-nebulization mode of FAAS, a number of elements can be successively determined in an extract. Another alternative sample preparation is to use microwave heating as a source of intense energy for rapid mineralization of liquid and solid samples. The reduction in the digestion time and the higher reaction speed may be due to the fact that the energy transfer is improved, and the microwave field has a specific chemical influence on organic molecules in acidic media. Generally, a few sources of systematic error should be considered. These include contamination, losses of trace elements, volatilization, and physical/chemical transformations of the samples.

4.2.2.2 Flow Injection Analysis

FIA has nowadays become a powerful analytical tool for sample preparation and introduction before measurement. It offers a convenient and fast approach to enhance and automate preliminary steps for atomic spectrometric detectors. Moreover, flow manifolds can ease the well-known problem of sample introduction to atomizers or even expand the classical scope of atomic/elemental information. Flow injection strategies with atomic spectrometric detectors are used in research and analytical laboratories. For detailed information, the reader is referred to a book by Sanz-Medel.

4.2.2.3 Interferences

In FAAS assay, minor ionization interferences may be encountered with Rb and Li in an air–acetylene flame and additional elements such as Al, Ba, Be, Ga, and Si in a nitrous oxide–acetylene flame. The interferences can be suppressed by adding ionization buffers. Background absorption is not a particular problem and is compensated for by using a deuterium background corrector. Sometimes, specific solute–volatilization interferences are observed in the determination of B, Ba, Cr, Mo, Pt, and Sn. They can be overcome by adding suitable spectrochemical buffers. Transport interferences are encountered with viscous sample solutions. Various nonspecific matrix effects are observed with nebulizing solutions of high salt and/or acid content. In such cases, acid-matched calibration and standard addition checks are advisable.

4.2.3 Applications

FAAS is a rather selective instrument for many metals. It has been used in a number of studies associated with occupational and environmental health. In a field investigation carried out at a North American nickel alloy production facility, the levels of worker exposures to inhalable and total nickel-containing aerosol during nickel alloy production were studied by Tsai et al. Worker exposures in a range of workplaces throughout the facility were assessed. The results showed that inhalable aerosol exposure levels for both overall aerosol and for total nickel were consistently and significantly higher than the corresponding total aerosol levels. In related work, Torjussen et al. investigated the concentration and distribution of heavy metals in nickel-exposed workers and of controls. Biopsy specimens from 30 nickel-exposed individuals and six controls were analyzed by FAAS to determine the content of nickel, copper, cobalt, zinc and iron. Some differences in epithelial types between specimens from the nickel-exposed group and the control group were seen.
Pilger and Broder\textsuperscript{146} reported a method that is suitable for assessing exposure to toxic metals in occupational indoor environments. The method has been evaluated for 21 metals including antimony, cadmium, chromium, cobalt, copper, lead, iron, zinc, and so on. The method is element specific. In another study, Bellido-Milla et al.\textsuperscript{147} detected hygiene hazards involved in naval industry welding processes. The metal contents of welding fumes produced at the shipyard were investigated to assess the hygiene hazards. Personal and environmental samples were collected on cellulose or polyvinylchloride filters. Samples were analyzed to encompass every possible working condition. Quantitative metal determinations were carried out by FAAS. The results obtained for metals and particles were compared and conclusions were drawn according to the type of welding procedure, sampling place, and use of fume extractor.

Burguera et al.\textsuperscript{148} reported the determination of lead in hair of exposed gas station workers and in unexposed adults by microwave-aided dissolution of samples and flow injection atomic absorption spectrometry (FIAAS). Lead content in head hair of 53 gas station workers together with an equal number of normal controls was determined. Samples of hair were washed with ethanol and water and were subject to microwave digestion prior to the determination of lead by FIAAS. The lead content in hair of the gas station workers (48.7 ± 17.5 µg g\textsuperscript{-1}) was significantly higher than that of the normal controls (17.2 ± 8.1 µg g\textsuperscript{-1}). The effects of washing and sample digestion procedures, head sampling site, hair color, age, smoking habits and duration of exposure to the metals were discussed. In related work, Othman\textsuperscript{149} had reported a preliminary investigation of the lead level in whole blood of normal and occupationally exposed populations in Damascus City. Tsalev et al.\textsuperscript{150} studied the manganese in whole blood of exposed workers and unexposed individuals in a manganese alloy plant. The purpose of this work was to elucidate the state of health of workers employed in a manganese industry.

4.3 Electrothermal-, Hydride Generation- and Cold Vapor Atomic Absorption Spectrometry

4.3.1 Principles and Instrumentation

An electrothermal atomic absorption spectrometry (ETAAS) system is equipped with a graphite tube, which is aligned in the spectrophotometer optical path, and is enclosed in an inert gas, usually argon atmosphere. The graphite tube furnace is electrically heated to preset “dry”, “ash”, “atomize”, and “clean-out” temperatures, so that it sequentially removes the solvent, organic matter/volatile matrix constituents, volatizes/atomizes the analyte, and eventually expels matrix/analyte residues. A transient peak signal is thus produced. Although graphite tube furnaces are most popular, there are also some other atomization devices such as carbon cups, Ta ribbon, Mo microtube, and so on. Graphite furnace atomic absorption spectrometry systems provide a 50-fold to 500-fold improvement in sensitivity relative to FAAS. Generally, an important ETAAS technique is to apply it to trace element analysis of biological samples with low limit of detections (LODs), and small size of samples. A typical ETAAS analysis is at nanogram per milliliter levels.\textsuperscript{140,141}

Hydride generation atomic absorption spectrometry (HGAAS) involves the generation of a volatile hydride of an analyte by means of a reducing agent added to a reaction vessel containing an acidic solution of the sample. The generated hydrides are transported to a heated atomizer cell, which can be a heated quartz tube or graphite tube. Sodium borohydride is most commonly used as a reducing agent. The thermally decomposed hydride produces atomic vapors that can be measured quantitatively. Since the hydride is separated from the matrix, advantages include high sensitivity and reduced interferences. However, this technique is only applicable to a limited number of elements. Those elements that form volatile hydrides include As, Se, Bi, Sb, and Te.\textsuperscript{140,141}

Cold vapor atomic absorption spectrometry (CVAAS) analysis is used for specific determination of mercury, which can exist in an atomic state at ambient temperature owing to its high vapor pressure. In a manner similar to HGAAS, a reducing agent is added to a reaction vessel containing a sample with trace levels of ionic mercury. Stannous chloride and sodium borohydride are the most commonly used reducing agents. Other constructions as well as automated continuous flow devices have been applied to biological samples.\textsuperscript{140,141}

4.3.2 Methodology

4.3.2.1 Sample Preparation The sample preparation for ETAAS and HGAAS measurements is not substantially different from that encountered in other atomic absorption spectrometry methods. Liquid–liquid extraction is highly suitable as a manual pretreatment procedure for HGAAS and speciation. The implementation of liquid–liquid extraction in a continuous fashion enables on-line coupling to AS instruments and contributes advantages inherent in automatic methods of analysis. A detailed technical description of continuous liquid–liquid extraction processes can be found in several books.\textsuperscript{140–143} Most biological samples are prepared by decomposing the sample using thermal or chemical means. The microwave approach for sample preparation is becoming a powerful tool. Calibration with standard
addition and verification of modified procedures by means of certified reference materials are often used.

4.3.2.2 Interferences ETAAS and HGAAS are methods of choice for the majority of elements. However, they have some drawbacks and limitations. Matrix effects in ETAAS are common, pronounced and complex. Therefore, background correction must always be provided. An adequate calibration is then required to compensate for residual discrepancies. Matrix/analyte modification techniques are commonly used and are aimed at either decreasing the relative volatility of the analyte or increasing the volatility of the matrix, or both. HGAAS has been applied to the determination of several volatile elements such as As, Se, Sn, Cd, Cu, and so on, which are not easily determined by flame and ETAAS. This technique is relatively selective and amenable to automation. In operation, the organic matter should be completely oxidized and the analyte should be in an oxidation state. Some potential interferences may be expected owing to acids, oxidants, and ions of noble metals. Their nature and extent depend on many factors such as acidity or pH, and the presence of oxidation states of both the analyte and the interferent. Generally, the important interferences and adverse effects can be reduced or eliminated by properly optimizing the experimental procedures.

4.3.3 Applications

Numerous papers have appeared that described application of ETAAS, HGAAS, and CVAAS methods to workplace occupational exposure studies. Rollin and Nogueira(151) reported identification of aluminum fractions in serum by Zeeman atomic absorption spectrometry in order to ascertain the distribution of aluminum (Al) in normal and occupationally exposed sera. It was found that the relative distribution of Al between high molecular mass and low molecular mass fractions was statistically significantly different. This suggests that at high concentrations of total Al in serum, the percentage of the Al bound to the low molecular mass is lower, but the absolute quantity of Al circulating as the low molecular mass complex is increased. This low molecular mass Al complex is thought to play an important role in intracellular accumulation of Al. In related work, Gitelman et al.(152) measured serum Al and urinary Al/creatinine ratios in 235 Al workers and 44 controls in the Al industry to examine the association between occupational exposure to airborne Al and Al absorption. Serum and urine samples were taken before and after 3–5-day work shifts. Occupational exposure was estimated from Al measurements of respirable and total particulates in air. Median exposure values were 25 and 100 µg m⁻³, respectively. These results are consistent with the systemic absorption of Al from occupational exposure, and suggest the presence of a sensitive uptake process for airway Al. In other related work, Rollin et al.(153) investigated the effect of exposure to Al on concentrations of essential metals in serum of foundry workers. The concentrations of Al in serum and urine of 33 volunteers exposed to inhalation of Al₂O₃ dust were measured. These were compared with results from 20 normal subjects not exposed. The Al concentration in serum was significantly raised in the subjects exposed to dust, but urine showed no significant difference from controls. This redistribution was selective, as the serum concentration of Cu was decreased whereas the serum concentration of Zn was increased. The serum concentration of Fe did not change significantly. Biological monitoring of occupational Al powder exposure was reported by Letzel et al.(154) Fifty-four workers from the exposed group were studied.

The measurement of salivary cadmium by ETAAS and its use as a biological indicator of occupational exposure has been reported by White et al.(155) The method has been developed and employed to measure cadmium levels in saliva samples collected by two different methods from a group of ex-workers previously exposed to cadmium, two groups of currently exposed workers, and an unexposed population as a control. Salivary cadmium levels were significantly raised in both of the groups of currently exposed individuals and in past workers with previous long-term exposure when compared with an unexposed population. In related work, Abernathy et al.(156) developed a method for measuring cellular Cd and DNA-bound Cd following micromolar exposures to cadmium dichloride. Following low-level exposure to cadmium dichloride, atomic absorption spectrometry with Zeeman background correction was used to measure total cell-associated Cd in wet-ashed cells. The lower LODs were determined to be 100 pg of Cd per 10⁶ cells. This method is sensitive and reproducible, and is suitable for the detection of Cd in biological matrices after low levels of Cd exposure. The determination of silver in whole blood and its application to biological monitoring of occupationally exposed groups were studied by Armitage et al.(157) Blood silver levels were determined in 98 occupationally exposed workers involved in bullion production, cutlery manufacture, chemical manufacture, jewellery production and silver reclamation. Other occupational applications of the ETAAS methods included study of urinary excretion of nickel in nickel–chromium electroplaters.(158)

HGAAS methods have been used in several studies of interest in occupational and environmental health. In a field investigation, Jensen et al.(159) reported the sum of concentrations of inorganic arsenic, methylarsonic acid and dimethylarsinic acid in urine from adults and children living in an unpolluted area. The results
from the unpolluted area were compared with the corresponding sum from adults and children living in an area polluted with arsenic, and the corresponding sum from persons occupationally exposed to arsenic. The median values for 22 adults and 10 children aged 3–10 years living in the unpolluted area were 9.3 and 19.8 nmol As mmol$^{-1}$ creatinine, respectively. The corresponding ranges were 3.2–27.9 and 7.7–57.8 nmol As mmol$^{-1}$ creatinine, respectively. The arsenic level in urine from adult workers handling arsenic-treated wood was approximately four-fold higher than controls. The arsenic levels in urine from two glass workers were nine- and two-fold higher, respectively. In another work, Blas et al.$^{160}$ developed a method for determination and speciation of arsenic in human urine by HGAAS. This method is applicable to urine samples in studies relating to arsenic exposure and its monitoring.

Another atomic spectrometric technique, the CVAAS method, has been used in mercury analyses. Martin et al.$^{161}$ reported a study of using spot urine samples for low-level occupational mercury exposure assessment, and demonstrated a relationship of Hg exposure with porphyrin and creatinine excretion rates. Hg and porphyrin levels in single void urine spot samples were compared with calculated 24-h urine levels in 35 practicing dentists who had been occupationally exposed to low levels of elemental Hg. The study aimed to determine the individual variability for Hg and porphyrin concentrations in spot samples over a 24-h period, and determine the time of day at which a spot sample would give an Hg concentration closest to the 24-h average concentration. The results confirmed previous reports of a first-order diurnal pattern with a mid-morning peak for Hg concentration. In other studies, the CVAAS method was also used in the determination and speciation of mercury, methylmercury, ethylmercury and phenylmercury concentrations in urine samples taken from students and staff of a dental workplace.$^{162}$

4.4 Inductively Coupled Plasma Atomic Emission Spectrometry

4.4.1 Principles and Instrumentation

The ICPAES technique has been available commercially since the mid-1970s.$^{163}$ The technique is an emission spectroscopic method in which the sample is dissociated into its atomic form and excited to high energy levels including the ionic form by introducing the sample into the center of a gaseous plasma sustained inside an induction coil energized with a high frequency alternating current. The excited species then emit characteristic radiation as they relax back to the atomic and ionic ground states. Principally, in ICPMS analytes are atomized, excited, and ionized, and then identified by their optical spectrum.

Today ICPAES has become widely accepted, and has been applied to elemental analysis of nearly all the elements. It offers simultaneous or rapid sequential multielement determination capability at the major, minor, and trace concentration levels. Because of its simplicity of use, wide linear dynamic range, and accuracy of analysis, it has become established as the accepted method for the analysis of metallic aerosols, powders of metals, dusts, and fly ashes.

4.4.2 Methodology

4.4.2.1 Sample Preparation

In multielement analysis by ICPAES, the dissolution of a sample can be quite complex. Like most classical chemical analysis and dissolution methods for atomic absorption spectrometry, the sample preparations are designed to bring the analytes into solution, without loss or gain. In general, there is no universal solvent or universal dissolution method. Knowledge of a wide range of sample types and dissolution procedures is needed to make a choice. When a large range of elements is under consideration, high temperatures can cause the loss of volatile elements, while low temperatures may result in the incomplete dissolution of refractory elements. Dry ashing methods can be used for large batches of samples, but there can be problems involving the loss of certain volatile elements. Acid digestion with either hot or cold is widely applicable to the analysis of a majority of elements. There are two groups of acids. One group includes oxidizing acids such as nitric, sulfuric and perchloric acids. Another group is nonoxidizing acids including hydrochloric, hydrobromic and hydrofluoric acids, and so on. Both groups can be used to dissolve metals, oxides, and carbonates. Microwave extraction or digestion is a safer, faster, cheaper procedure, and causes less contamination of sample prepared for trace analysis. It is increasingly replacing conventional techniques such as hotplate acid digestion. For a particular sample type, a specific method should be developed through experiments in which the acid mixture, the microwave power setting, and the heating period are varied to determine which combination gives the best results. Because ICPAES can tolerate high levels of organic material, the complete destruction of organic material is not necessary.

4.4.3 Applications

Many papers have been published that deal with the measurement of metals of interest in workplace air, or dust, and in biological monitoring by ICPAES. Lo and Arai$^{164}$ developed a rapid method for the simultaneous determination of 11 metals (As, Be, Cd, Co, Cr, Cu, Hg, Mn, Ni, Pb and Zn) in urine by
ICPAES. Acidification of the urine was the only sample preparation required. This procedure has been applied for routine screening of workers for occupational exposure to toxic metals. Biological exposure evaluation and hair analysis in workers handling chromium compounds were reported by Kudo et al.\textsuperscript{[165]} The hair of 40 workers exposed to chromium compounds was analyzed for 18 elements by ICPAES; 21 subjects worked in a factory that manufactured chrome pigments, 11 in a painting factory and 8 in a Cr plating factory. It was found that simultaneous measurements of Cr in the hair and urine were useful for determining the extent of exposure to Cr. Determination of multiple elements should be the best means of estimating the degree of exposure to Cr compounds in which they are found.

Olson et al.\textsuperscript{[166]} described trace element analysis of As, Be, Cd, Cr, Cu, Fe, Pb, V, and Zn in airborne particulates and in human urine by ICPAES. The principle of the method, range and sensitivity, interferences, accuracy and precision, advantages and disadvantages are detailed in their paper. Franzlau\textsuperscript{[167]} used ICPAES in screening for trace metal exposures in an industrial population. A heterogeneous group of asymptomatic industrial workers were examined and had hair and blood samples analyzed for 10 metals via the ICPAES technique. Hull\textsuperscript{[168]} employed ICPAES for the multielement analysis of industrial hygiene samples. Experiments were conducted to define the lower limit of quantitative determination and the analytical range of each element for which an OSHA (occupational safety and health administration) personal exposure limit exists. The effects of varying solution matrices and interelement effects were investigated. Cadmium emissions from fumes were studied during processing of Cd-containing thermoplastics processing. Air sampling volumes of 120–388 L were collected in the door area, at the machine nozzle and mold vent, and 1 m away from the machine approximating the position of the operator, and analyzed for Cd by ICPAES.

5 CHROMATOGRAPHIC SPECTROPHOTOMETRIC DETECTORS

5.1 Introduction

Spectrophotometric detectors coupled to chromatographic separation techniques are often used to characterize the workplace environment. These techniques are employed\textsuperscript{[169]} to confirm the accuracy of direct reading instruments or when direct reading instruments are not available or when the workplace environment is complex and contains multiple chemicals that need to be measured for regulatory documentation of exposure levels\textsuperscript{[170]} and for biological monitoring.\textsuperscript{[171]} Standardized methods are published by a variety of government agencies and societies, including the National Institute of Occupational Safety and Health (NIOSH), OSHA, Mine Safety and Health Administration (MSHA), Environmental Protection Administration (EPA), and American Society for Testing and Materials (ASTM). Many of these methods can now be obtained through the Internet. The NIOSH Manual of Analytical Methods can be found at www.cdc.gov/niosh/nmam/nmampub.html. This site also contains links to the other organizations mentioned. Harper et al.\textsuperscript{[169]} have reviewed the literature published in the field of industrial hygiene. Many references to specific air monitoring and biological techniques are sited within this review. The following is a short overview of chromatographic spectrophotometric detectors, emphasizing UV/VIS and fluorescence detectors.

5.2 Spectrophotometric Detectors for High-performance Liquid Chromatography

Spectrophotometric detectors that can be coupled to HPLC include UV/VIS, fluorescent, light scattering, refractive index, diode array, MSD, IR detectors, radioactivity and luminescence. The choice of detector is dependent on the analyte’s spectral properties, and required sensitivity and selectivity. Both the sensitivity and selectivity of spectroscopic detectors are dependent, in part, on wavelength(s) employed. The wavelength where maximum absorption occurs for the chemical of interest may not necessarily be used to quantify levels in a particular occupational environment if chromatographically coeluting contaminants absorb at that wavelength. The settings may be changed slightly or moved to a secondary absorbance peak of the analyte to eliminate the interference. Wavelength selection can also be limited by mobile-phase requirements for chromatographic separation of the environmental components of interest. Water, methanol and acetonitrile are mobile phases used in reversed-phase HPLC with ultraviolet cutoff points of \(\leq 210\) nm. Choice of detector can also be influenced by the linearity and dynamic range (concentration versus detector response) requirements. It is desirable to choose a detector with a wide linear working range to be able to assess both major and minor chemical components in the workplace environment. Comparison of detector sensitivities for a particular analyte can be made by using the LOD, which is reported as the amount of analyte that provides a signal that is two to three times that of background noise.

The most commonly employed HPLC detectors in monitoring the workplace environment are the UV/VIS photometric and fluorescent detectors. UV/VIS detectors are available as fixed, variable and scanning-wavelength detectors. Diode array detectors, which...

<sup>a</sup> UV, ultraviolet; fluor, fluorescent; 2,4-D, 2,4-dichlorophenoxyacetic acid; 2,4,5-T, 2,4,5-trichlorophenoxyacetic acid.

<sup>b</sup> Fluorescent wavelengths are given for excitation/emission.

Table 4 provides simultaneous spectral data on each peak eluted from the column, are increasingly being employed. Sensitivity of UV/VIS detectors is limited by the detector flow cell path with respect to volume restrictions. In general, the detector cell volume for standard column HPLC should be no greater than 8 µL cm<sup>–1</sup> of the optical path length. Sensitivity for an analyte can be enhanced by conjugation of chemical functional groups to specific chromophores.

Fluorimetric detectors are considered, in general, to provide better selectivity and sensitivity than UV/VIS detectors, although both UV/VIS and fluorimetric detectors are available for HPLC detection. The emitted light is usually measured at right angles to the excitation source. The enhanced sensitivity in fluorescence techniques over absorption detectors is mainly due to the reduction in noise caused by background light. Flow cells for fluorimetric detectors must optimize excitation and emission collection efficiency for the small volume of the cell. This requires use of a high-intensity excitation light that is usually provided by mercury or xenon arc lamps. Lasers are becoming more commonly employed as the excitation source. They can focus a high intensity beam onto a small capillary cell and the intensity of the source does not decay with age as seen with traditional excitation lamps. Lasers that emit light in the lower ultraviolet ranges, at present, are very costly, which has limited the spectrum of analytes and conjugates that have been employed with this technique. Secondary excitation/emission wavelengths can be used if interferences are encountered and derivatizing agents can be conjugated to a nonfluorescent analyte to allow for detection. This can improve the LOD for an analyte from 1 to 3 orders of magnitude over UV/VIS detection.

Table 4 is a list of HPLC/ultraviolet and fluorescent methods from the NIOSH Manual of Analytical Methods (4th edition) for chemical analysis of air samples. The majority of the methods take advantage of UV and/or fluorescent spectral properties of the analyte. The 254-nm wavelength is standard on fixed wavelength detectors, because of the broad range of chemicals that absorb at that wavelength. Many methods in the past...
have been developed using 254 nm as the detection wavelength because of this. Derivatization to stabilize and/or enhance spectral properties is used in several of the methods. Naphthylisothiourea derivatives are employed for the measurement of ethylenediamine, diethylenetriamine, and triethylenetetramine (method number 2540), and 2,4-dinitrophenyldrazone formaldehyde conjugation in method number 5700. Isocyanates are derivatized to a stable form for analysis by either ultraviolet or fluorescent detectors. Newer reagents have been developed for trapping and detection of isocyanates, such as 1-(9-anthracenylmethyl)piperazine, 9-(methylaminomethyl)anthracene, 1-(2-methoxyphenyl)-piperazine and dibutylamine, because of the potential exposure to multiple polymeric forms. These reagents employ UV, fluorescent and/or MSDs to give a fingerprint of the multiple polymer isocyanate exposure.

5.3 Spectrophotometric Detectors for Gas Chromatography

Spectrophotometric detectors for GC include MSD, IR, FPDs, and chemiluminescence–redox detectors (CRDs). The majority of the GC applications for industrial hygiene are based on flame ionization detectors, however, the MSD is becoming increasingly common for both air and biological marker analysis. Flame photometric detectors (FPDs) are highly selective for both phosphorus and sulfur. Phosphorus-containing compounds are detected at 510 and 526 nm. Sulfur species emits light at around 394 nm. Applications for the FPD include analysis of pesticides and sulfur-containing gases and fuels.

FTIR is often used to complement the MSD and can provide functional group data and an IR fingerprint to help identify unknown components in the workplace environment or a chemical metabolite following exposure. The traditional light pipe FTIR instrument is relatively insensitive. This has limited its application to mainly qualitative analysis, e.g. identification of trichothecene mycotoxins in bulk samples. One commercially available FTIR instrument has employed direct deposition of the analyte onto a moving ZnSe window to improve detectability into the picogram (of dodecane) range. This increase in sensitivity should allow for the development of applications for qualitative and quantitative analysis of the workplace environment through both air and biological sampling.

CRDs are useful for compounds that are poorly detected by FPDs. The CRD detects the resultant chemiluminescence following specific redox reactions of compounds such as ammonia, sulfur dioxide, and thiols. A variety of other speciality spectroscopic detectors are available, including pyrochemiluminescent nitrogen and pyrofluorescent sulfur detectors that have been used for specific types of analyses. These detectors convert nitrogen-containing compounds to nitric oxide (NO) and sulfur-containing compounds to sulfur dioxide (SO2). The NO is reacted with ozone to form the excited state of NO2+, which releases a photon of light.

6 INFRARED AND RAMAN SPECTROSCOPIES

6.1 Introduction

Emissions of hazardous chemical pollutants are concerns in both the environment and the workplace for safety reasons. Identification of chemical pollutants in these places can be accomplished by various techniques. IR spectroscopy, especially FTIR, and RS are the techniques of choice for the identification of the majority of chemical pollutants. Many pollutants have chemical groups of toxicological importance that can be identified and quantified by IR or RS, which measures the vibrational excitation of atoms around the bonds that connect them.

Although IR and Raman spectroscopies are similar in that both techniques provide information on vibrational frequencies, there are many differences between the two techniques. Some vibrations are only Raman active while others are only IR active; the vibration of a heteropolar diatomic molecule is IR active, whereas that of a homopolar diatomic molecule is not IR active. In molecules having a center of symmetry, a vibration is IR active, Raman active, or active in both; however, totally symmetric vibrations are always Raman active.

In IR and Raman, the spectra range from 4000 to 50 cm\(^{-1}\). In both vibrational spectroscopies, the small quantity of samples needed, the speed with which a spectrum can be obtained, and the wide applicability of the methods combine to make IR and Raman spectroscopies two of the most useful tools available to the chemist, industrial hygiene chemist, and industrial hygienist. Both spectroscopies have a great potential because of their applicability to many different fields, such as in structural chemistry, biology, biochemistry, medicine, and industry. In the following, some specific applications of FTIR and Raman spectroscopies in occupational and environmental hygiene chemistry are presented.

6.2 Infrared Spectroscopy

6.2.1 Fourier Transform Infrared Spectroscopy for Monitoring Airborne Gas and Vapor Contaminants

With the increased use of highly toxic gas and vapor mixtures in science and industry, the need has come for more
sensitive and versatile air monitoring technologies. Of the instruments that are appropriate for industrial hygiene monitoring of gases and vapors cited herein, \(^{(182-184)}\) only FTIR spectroscopy is presented in the following discussion.

In the 1990s, a number of IR instruments have been developed, including filter, optical null and ratio recording grating, Fourier transform, and tune laser diode spectrophotometers. \(^{(185)}\) FTIR has been shown to be particularly valuable in the monitoring of airborne gas and vapor contaminants. \(^{(186)}\) The earliest applications of IR spectroscopy for the identification and quantification of pollutants in air were made using a long-path gas cell. Stephens et al. employed a prism spectrometer (with thermocouple detectors) to measure atmospheric chemistry related to smog pollution. \(^{(187)}\) In later studies with an FTIR long-path system, Tuazon et al. studied trace gases in ambient air and synthetic atmosphere. \(^{(188)}\) Herget and Levine \(^{(189)}\) used an FTIR spectrometer with a 20-m gas cell as a near real-time monitoring method for semiconductor process gas emissions. Some other research has been carried out using FTIR for measurement of mobile source emissions. \(^{(190)}\) polluted urban air, \(^{(191)}\) and reactivity of hydrocarbons. \(^{(192)}\) Many studies have utilized remote sensing FTIR to provide reliable air pollution information. \(^{(193,194)}\) In remote systems, the gas cells are replaced by telescopes that are used to collimate, send, and receive IR light. With an interferometer system, which employed telescopic optics, the remote sensing FTIR has been used to measure the concentration of gaseous pollutants ranging from 10 ppm to 1 ppb over a 1-km path length. \(^{(195)}\)

An open-path FTIR system has been developed to monitor gas and vapor contaminants quantitatively in the workplace. \(^{(196)}\) This system was tested in the workplace to monitor numerous organic vapors, such as ammonia, methanol, methylene chloride, and sulfur hexafluoride. \(^{(197)}\) An open-path FTIR system has also been applied to air pollution monitoring of trace gases in ambient air. \(^{(198)}\) The ability of open-path FTIR instruments to monitor multiple compounds in real time makes it an ideal industrial air monitoring instrument.

6.2.2 On-filter Analysis of Quartz in Respirable Coal Dust Using Fourier Transform Infrared

The method for determining quartz content in respirable coal dust is based on dispersive IR spectroscopy. \(^{(199)}\) This method has been adequate for many years with a working range capable of measuring 25–250 µg of quartz. A development of the FTIR method is that 10 µg of quartz can be detected in coal dust samples. \(^{(200)}\) FTIR employs an interferometer to obtain information about the transmission of IR energy of all wavelengths emitted by the source and passing through the sample. Since there are no entrance or exit slits in FTIR, a greater amount of energy reaches the detector, resulting in increased sensitivity. The interferometer in FTIR contains a fixed mirror and a moving mirror, and the laser tracking of the moving mirror results in greater precision of the wavelength measurement. This permits multiple scans to be averaged, so the signal-to-noise ratio of the FTIR spectrum increases. The quantitative FTIR analysis of quartz in respirable coal dust samples collected on filters would provide the analyst with many benefits, such as speed, convenience, and productivity. \(^{(201)}\)

Min-U-Sil 5 (US Silica Co.) quartz dust (pure quartz particles, 5 µm or smaller) is used as the standard for FTIR analysis. \(^{(199,202)}\) Polyvinyl chloride or acrylonitrile copolymer filters used for this study have a pore size of 5 µm or less. The filter diameter must be appropriate to the sampler used. The dust samples are collected on the filters. After ashing the membrane filter, the dust samples are dispersed into isopropyl alcohol. Details of the sample treatments and filtration procedure are described by Tuchman. \(^{(203)}\) Calibration samples, using Standard Reference Material, \(^{(204,205)}\) are prepared over the range of 2–20 µg. \(^{(206)}\) The filter samples are placed in the filter holder to be analyzed by FTIR. The routines for determining quartz using FTIR are the same as described by Tuchman. \(^{(207)}\) The FTIR bands of the quartz spectrum have been reported at 1087, 799, 780, 695, 524, and 467 cm\(^{-1}\). \(^{(208)}\) These band intensities as shown in the quartz absorption spectrum occur closer to the far-IR region and are not obscured by random noise. However, the absorption band at 1087 cm\(^{-1}\) is strong but very broad while the 695 cm\(^{-1}\) is weak; therefore, these two bands are problematic for quantifying quartz. The remaining four bands at 799, 780, 524, and 467 cm\(^{-1}\) are suitable for quantifying quartz.

6.2.3 Studies on Structural Changes of Collagen in Silicosis Using Fourier Transform Infrared

Silicosis is a well-known occupational disease that continues to spread even after exposure to dust stops, and there is no effective treatment. Therefore, prevention of exposure to dust pollutants and early detection in the work environment are required. Although studies on structural changes of collagen in silicosis can be accomplished by several techniques, \(^{(204,205)}\) only studies on structural changes of silicotic collagen using FTIR are presented as follows. Test samples in the lung, lymph node, and other various tissues of normal and silicosis-affected humans or animals are used for FTIR studies. \(^{(206)}\) The tissues are fixed in KBr as described by Yurui et al. \(^{(206)}\) The wavenumber of FTIR spectroscopy
6.3 Raman Spectroscopy

Like IR, RS is a powerful technique and has a variety of applications. IR and Raman spectroscopies are complementary, and both are utilized whenever possible. Since experimental techniques and applications of RS have been reviewed extensively, only microscopic inclusions caused by inhaled particles (including talc, rutile, α-quartz, and calcite) which have been identified in situ by Raman microspectroscopy are covered. Other experimental techniques and their applications should be referred to: nonlinear RS,\(^{208}\) time-resolved RS,\(^{209}\) matrix-isolation RS,\(^{210}\) high-pressure RS,\(^{211}\) Fourier transform RS,\(^{212}\) surface-enhanced RS,\(^{213}\) and Raman spectroelectrochemistry.\(^{214}\)

6.3.1 Experimental

The sample being studied is placed on the stage of the microscope and illuminated by light from the transmission illuminator. The sample is focused and adjusted by viewing from the optical viewpoint. Then, the illuminator lamp is switched off and the laser beam is passed through filtering optics. The scattered light from the sample is collected by the objective and sent into the spectrometer. A cooled photomultiplier detector is used for detection.

6.3.2 Identification of Inhaled Particles, Including Talc, Rutile, α-Quartz, and Calcite

6.3.2.1 Identification of Talc

A pure talc particle (talcum powder), used as a reference, and test particle samples in the foreign bodies in various tissues\(^{215}\) that contain a talc particle (both are about the same size, 5–10 µm) are used for RS. The tissue samples are fixed in formaldehyde, dehydrated, and embedded in Paraplast™ as described by Mul et al.\(^{216}\) Sections of paraffin-embedded material are placed on the stage of the microscope for Raman measurements and control purposes. The wavenumber for RS ranges from 4000 to 50 cm\(^{-1}\). The Raman peaks of the reference spectrum have been reported at 115, 197, 366, 679, and 1049 cm\(^{-1}\).\(^{217}\) The 197 and 679 cm\(^{-1}\) bands as shown in the reference spectrum\(^{217}\) are very strong, the 115 and 366 cm\(^{-1}\) bands are strong, and the 1049 cm\(^{-1}\) band is medium. A direct comparison between the test sample spectrum and the reference spectrum (the peak positions and their relative intensities) is sufficient to make an assignment for the talc particle.

6.3.2.2 Identification of Rutile (TiO\(_2\))

A pure rutile particle, used as a reference, and test particle samples in the foreign bodies in various tissues\(^{215}\) that contain a rutile particle (both are about the same size, 5–10 µm) are used for RS. The tissue samples are fixed and placed on the stage of the microscope as described above. The wavenumber of RS ranges from 4000 to 50 cm\(^{-1}\). The Raman peaks of the pure rutile spectrum have been reported at 240, 440, and 610 cm\(^{-1}\).\(^{218}\) The 240, 440, and 610 cm\(^{-1}\) bands as shown in the pure rutile spectrum\(^{218}\) are broad, and their intensities are medium. A direct comparison between the test sample spectrum and the pure rutile spectrum (the frequencies, relative intensities, and linewidths) is sufficient to make an assignment for rutile in test particle samples.

6.3.2.3 Identification of α-Quartz (SiO\(_2\))

A reference particle and test sample particles in the foreign bodies in various tissues\(^{215}\) that contain α-quartz particles (both are about the same size, 5–10 µm) are used for RS. The tissue samples are fixed and placed on the stage of the microscope as described above. The typical peaks of a reference spectrum have been reported at 128, 206, and 466 cm\(^{-1}\).\(^{219}\) The 128 and 466 cm\(^{-1}\) bands as shown in the reference spectrum\(^{219}\) are sharp, and the 206 cm\(^{-1}\) band is broad. A direct comparison between the test sample spectrum and the reference spectrum (the peak positions, shape, and their relative intensities) is sufficient to make an assignment for α-quartz samples.

6.3.2.4 Identification of Calcite

Test particle samples and a reference particle in the foreign bodies in various tissues\(^{215}\) that contain a calcite particle (both are about the same size, 5–10 µm) are used for RS. The tissue samples are fixed and placed on the stage of the microscope as described above. The Raman peaks of a reference spectrum have been reported at 156, 285, 715, and 1088 cm\(^{-1}\).\(^{220}\) A direct comparison between the test sample spectrum and the reference spectrum (the spectral positions and line shape) is sufficient to make an assignment for the calcite particle.
7 FIELD-PORTABLE SPECTROSCOPY

7.1 Introduction
Field-portable methods for monitoring airborne workplace contaminants and toxins have received increasing attention. A number of portable monitors for airborne contaminants have been commercially available for many years, but new developments may provide for on-site compliance monitoring, which has heretofore been more the exception than the rule. The ability to conduct measurements on-site in the occupational setting offers significant advantages. Field-portable methods are often desired so that decisions regarding worker protection, engineering controls, and so on can be made quickly. The capability for rapid decision-making offered by on-site monitoring can help to save costs, and also offers a means to assess, and thereby provide timely prevention of, worker overexposures to toxic substances. Field-based monitoring is especially useful for applications in the construction industry, in agriculture, and in other situations where jobs may be short term and the workforce is transient. On-site techniques can also be beneficial in instances where short-term monitoring is desired. In this section, field-portable spectrometric techniques are covered, and some applications are presented. Because of limited space here, a general overview is presented; more specific information is available by consulting the literature referenced herein.

7.2 Portable Gas and Vapor Analyzers
While many commonly used portable gas and vapor analyzers are based on electrochemical or electrical measurement, some rely on spectrometric means. Direct-reading instruments which rely on the use of IR, fluorescence, luminescence, or colorimetry have proven to be most popular. Other spectrometries have also been used for on-site real-time gas and vapor monitoring. Some portable instruments, e.g. IR, allow for multigas detection, while others are designed for the measurement of single species of interest, such as carbon monoxide or ozone. Table 5 summarizes direct-reading spectrometric devices that are commonly used in the industrial hygiene field for monitoring gases and vapors. A wide variety of commercial instruments are available.

Most portable IR gas analyzers are nondispersive IR instruments that ordinarily require a plug-in power source. Some dispersive instruments have also been introduced. Battery-powered instruments have been produced, but these are generally species-specific; for instance, an IR photometer for monitoring carbon dioxide over a wide concentration range relies on Ni–Cd batteries as an optional power source. Portable multigas IR analyzers are becoming more popular as their applicability is enhanced through interfacing of the instrument with spectral libraries via computer. A wide variety of organic and inorganic gases can be monitored semiquantitatively or in some cases quantitatively. For example, portable IR monitors for CO are able to measure quantitatively this dangerous compound in the parts per million range, where such concentration levels are potentially hazardous to life and/or health.

Field-portable FTIR instruments are now available and a national voluntary consensus standard has been published which describes a portable FTIR method for determining gaseous compounds. IR or FTIR monitoring allows for real-time or near real-time measurement of numerous toxic gases and vapors, and has applications in many occupational settings. An advantage of IR or FTIR monitoring is that sample preparation is minimal, and gases and vapors may be monitored following sampling by using a suitable sampler; or alternatively no samples may be needed at all (depending on the application). Open-path FTIR for real-time in situ monitoring of airborne gaseous pollutants has become popular for remote sensing, and also offers promise for applications in occupational settings. A new IR spectral database standard, National Institute of Standards and Technology (NIST) SRM 79, has been made available recently.

This NIST IR database contains absorption coefficient data for 21 hazardous air pollutants, and provides for quality assurance for quantitative FTIR open-path in situ measurements of these species.

Colorimetric and UV/VIS spectrophotometric monitors for gases and vapors are widely used in the industrial hygiene field (Table 5). Most of these monitoring devices, e.g. for ozone, mercury vapor, NOx, ammonia, and sulfur dioxide, function by means of ultraviolet absorption.\(^{222,233}\) Colorimetric monitors ordinarily employ a reaction between a selective reagent and the analyte of interest in order to form a colored complex which can be measured in the visible spectral range. Most commercially available colorimetric and UV/VIS photometers require an external power source for their operation. However, there are examples of such portable devices that can be operated using battery power, e.g., some Hg and SO2 monitors. Portable, battery-powered devices are useful for personal monitoring, while monitors requiring an external power source are limited to use as area (static) monitors. UV/VIS and colorimetric instruments are able to detect most species of interest in the parts per million range, and many are equipped with alarms if readings are high. Many of the UV/VIS direct-reading instruments offer continuous monitoring capability, with response times of \(~1\) s for measurements in the parts per million range.

Direct-reading chemiluminescent detectors offer a means for measuring ozone and oxides of nitrogen, with excellent specificity and high selectivity (Table 5). The operation of chemiluminescent detection involves excitation of \(O_3\) molecules via chemical reaction and the subsequent detection of photon emission from the excited state species, which may either be an intermediate or a product of the reaction.\(^{234}\) Ozone may function as a reagent for NOx analysis or, of course, as the analyte of interest.\(^{235}\) Luminol has also been used for field-portable monitoring of NOx,\(^{236}\) and ethylene has been employed as a reactant for field-portable monitoring of ozone.\(^{237}\) Owing to high power needs, field chemiluminescence instruments generally require an external power source.\(^{222,228}\)

Photometric analyzers are used widely in the industrial hygiene field for the on-site, real-time monitoring of numerous gas and vapor species (Table 5). The operation of the detector is via measurement of light emission from a high-temperature \(H_2\) flame.\(^{238}\) FPDs are useful for selective measurement of gaseous sulfur or phosphorus compounds, with detection limits in the parts per billion range for these species. The high power required for operation of these devices necessitates the use of an external power source.

Portable photoionization detectors (PIDs) for organic vapors are commercially available.\(^{239}\) These require less power than the aforementioned photometric analyzers, and simple hand-held, battery-powered devices can be used to monitor volatile organic compounds (VOCs) in real time. However, for enhanced performance (such as minimizing interferences from more abundant hydrocarbons), PIDs can be used as detectors for portable GC instruments.\(^{240}\)

Fluorescence analyzers are available for monitoring CO and SO2 (Table 5). An Xe or Hg arc lamp is used to excite the analyte species, which give rise to sufficient fluorescence intensity so that detection limits in the few parts per billion range can be achieved.\(^{222}\) Photomultiplier tubes are used for detection. Like photometric analyzers, there is a need for high power in order to facilitate source excitation and operation of photomultiplier detectors, and thus an external power source is required. The performance of the portable fluorimetric SO2 analyzer has been shown to be equivalent to that of a colorimetric reference method promulgated by the EPA.\(^{228}\)

Other types of photometric analyzer are commercially available, whereby alternative chemical strategies may be used to produce a spectral signal or color change.\(^{222}\) Spectral intensity analyzers, for example, can be used for general, nonspecific monitoring of halogenated hydrocarbons. Other types of photometer allow for automated sampling by use of media which undergo a color change upon reaction with target analytes (e.g. like that already mentioned for monitoring SO2). Reflectance may be used for the measurement of a variety of species such as ammonia, phosgene, HCN, and arsine, with detection limits in the parts per million range. In a few cases, field portability and on-site monitoring applications are enhanced by the use of battery power instead of an external power source.

New developments in spectrometric gas and vapor monitors have provided for better detection limits and other attributes. Fiber optic chemical sensors for continuous monitoring have been an area of wide interest,\(^{241}\) and applications in the measurement of gases and vapors are widespread. Fiber optics have proven to be useful for the design of field-portable devices for optical,\(^{242,243}\) fluorimetric,\(^{244}\) and IR\(^{245}\) monitoring of such species as VOCs, Hg, explosive agents, and so on. The use of optical sensor arrays for multispecies monitoring is also an area of significant promise.\(^{246}\) Miniaturization of TOF mass spectrometric devices has allowed for the on-site monitoring of gaseous analytes, with excellent prospects for multispecies monitoring.\(^{247}\) Hand-held ion mobility spectrometry (IMS) instruments have found applications in industrial hygiene and military applications.\(^{248}\) A hand-held IMS device was used to monitor VOCs on-site in the workplace.\(^{249}\) The
performance of IMS is enhanced when used as a detection scheme following GC separation.\(^{250,251}\)

### 7.3 Portable Aerosol Monitors

Direct-reading portable aerosol monitors which are used for industrial hygiene purposes are often based on light-scattering or light-attenuation properties (Table 6). The most widely used are light-scattering devices known as aerosol photometers or nephelometers.\(^{223}\) Light-attenuating photometers are also available, as are other real-time aerosol monitors that are not based on optical techniques.\(^{252}\) Portable instruments have been developed which are applicable over different aerosol size ranges (Table 6) and each device has its own benefits and limitations.

Aerosol photometers operate by directing polychromatic light toward an aerosol as it is passed through an optical chamber, and by measuring the light which is scattered at a chosen scattering angle with respect to the incident light beam. Optical aerosol particle counters use a monochromatic light source such as a laser, photodiode or tungsten filament lamp to illuminate the aerosol sample. For both photometers and optical particle counters, photomultiplier tubes or photodiodes are generally used for detection of the scattered light. Smaller scattering angles are best for the detection of large particles, while a scattering angle of 90° offers maximum sensitivity for small particles.\(^{223}\) Many factors contribute to the light scattering profile, e.g. wavelength of the incident light beam, size and shape of the particles, refractive index of the particle, density and concentration of the aerosol, and size distribution of the aerosol.\(^{253}\) Thus it can be seen that these devices may suffer from numerous limitations which can restrict their applicability for quantitative monitoring, and therefore are generally not used for compliance monitoring purposes. Nevertheless, they are very useful for applications as on-site screening instruments and semiquantitative measurement of aerosol concentrations.

Several popular instruments for estimation of aerosol concentrations in real-time are based on light-scattering methods, and a variety of techniques have been employed to improve their performance.\(^{223,254}\) Techniques for sampling and analysis have been developed for both “extracted” samples and for in situ analysis.\(^{252}\) Several devices utilize monochromatic IR or near-IR radiation to illuminate the sample, and some employ size-selective devices in order to isolate the aerosol range of interest. These devices are generally applicable for monitoring aerosols which are about 1.0 µm in diameter or greater, and are therefore not useful for the detection of small diameter aerosols. However, some have been claimed to give accurate aerosol concentration measurements over the range of 0.01–100 mg m\(^{-3}\) for aerosols of 0.1–20 µm in diameter.\(^{223}\)

For measurement of very small aerosols, condensation nucleus counters (CNCs) are usually employed (Table 6). The CNC functions by actually enlarging the aerosol particles to a size which can be measured photometrically.\(^{223,252}\) This is usually accomplished by subjecting the ultrafine aerosol to a vapor, and then cooling the mixture to cause supersaturation. In this manner the aerosol particles operate as condensation nuclei upon which the supersaturated vapor can nucleate and cause the aerosol particles to grow in diameter. In so doing, the intensity of scattered light can be used to measure the concentration of the enlarged particles. CNCs are widely used for testing high-efficiency particulate air filters in respirator fit-testing.\(^{255}\)

With some exceptions, real-time aerosol monitors are survey instruments which can only be used to measure total concentrations of airborne particulates. Furthermore, the size ranges of aerosols which real-time aerosol monitors can measure tend to be limited.\(^{256}\) Direct-reading, real-time aerosol monitoring instruments generally cannot give any information on the identities of airborne contaminants which may be present in the test aerosol. However, in recent instrument developments, efforts have been made to obtain more species-specific information using real-time optical monitoring. For example, a real-time monitor for respirable particles based on laser light scattering was said to be capable of detecting 0.1 fibers cm\(^{-3}\) with very short sampling times.\(^{257}\) The instrument uses a diode array to sense scattered light and then assigns a particle to a particular class depending on its scattering characteristics. In most direct-reading instrumental applications, knowledge about the specific makeup of the aerosol being monitored is necessary before a survey instrument is employed.

Portable methods for measuring chemical species in captured aerosols ordinarily require that an aerosol sample be prepared and analyzed on-site in the field. In some cases sample preparation may be minimal, while

in other instances considerable sample treatment may be needed prior to on-site analysis. The option of using a field-portable analytical method depends on the needs of the user. If it is desirable to have an analytical result quickly, then it may be necessary to perform on-site analysis. Another possible reason for conducting analysis on-site has to do with the reactivity of target analytes which can exist in the sampled aerosol. Reactive compounds may need to be analyzed quickly in the field using field-portable instrumentation, because the chemical form(s) of the analyte(s) of interest may change if samples are stored for too long a time period (e.g. for subsequent fixed-site laboratory analysis).

Various field-portable spectrometric techniques for on-site determination of heavy metals in collected aerosol samples have been evaluated. For instance, portable X-ray fluorescence (XRF) has been used to measure metal species in air filter samples. In one study, portable XRF was used to determine metals in filters which were prepared from aerosolized metal oxides. Reactive compounds may need to be analyzed quickly in the field using field-portable instrumentation, because the chemical form(s) of the analyte(s) of interest may change if samples are stored for too long a time period (e.g. for subsequent fixed-site laboratory analysis).

In related studies, modern portable XRF devices have been used to determine lead in filter samples, with a view toward obtaining lower detection limits for this metal. In one investigation, air filter samples were collected from construction sites where lead paint removal activities were undertaken. The lead loading range of the data set was 0.1–1500 µg of lead per sample. Portable XRF measurements were conducted on the filter samples using a protocol which accounted for the variability in the density of the aerosol which was deposited on the filters. A NIOSH reference technique, graphite furnace atomic absorption spectrometry, was used for confirming analysis and method evaluation purposes. For the portable XRF method, a lower detection limit of ~6 µg Pb/filter was determined, and the portable XRF method accuracy was ±16.4%. The performance of the portable XRF instrument indicated that the device can be used for the quantitative analysis of lead air filter samples over a wide concentration range. The practicing industrial hygienist can use portable XRF to produce a rapid on-site determination of lead exposure and immediately communicate to workers and help identify appropriate levels of personal protection.

Some other techniques that offer promise for on-site multielement spectrochemical analysis include laser-induced breakdown spectroscopy (LIBS) and spark-induced breakdown spectroscopy. While neither instrument has been commercialized, prototypes of both have been evaluated for their ability to determine a number of heavy metals in air samples. For metals such as lead, LIBS may offer lower detection limits than portable XRF devices. Efforts to make prototype LIBS devices more easily field portable have focused on the use of fiber optics.

Spectrometric methods for the on-site analysis of species present in aerosols following a sample dissolution step have been published. For example, a field-portable method for the determination of airborne hexavalent chromium, Cr(VI), was developed and evaluated. The procedure employed ultrasonic extraction in order to solubilize Cr(VI) in test samples. Subsequently SPE using strong anion exchange was employed to separate Cr(VI), which is anionic, from Cr(III) and other metal cations. Following elution of the isolated Cr(VI) trace concentrations of Cr(VI) were measured using the diphenylcarbazide method by means of a field-portable battery-powered spectrophotometer. It is expected that additional field-portable spectrometric measurement methods for more analytes will become more widely used in the future for industrial hygiene monitoring.

### 1 Introduction

Historically, most toxic exposures have been categorized using air monitoring techniques because occupational and environmental standards for chemicals were based on air concentrations. However, air sampling will not measure the total exposure to chemicals capable of penetrating the skin. Skin contamination can occur as a result of fallout from aerosols, via direct immersion into the chemical, as a result of accidental spills onto the body, through vapor penetration of the skin, or from contact with contaminated surfaces. Such contamination can produce the same types of toxic effects as inhalation exposure if a chemical can significantly penetrate the skin. Surface contamination can be ingested orally, create airborne exposures when surface buildup is disturbed, and be transferred into other areas, including from the workplace to the home.

Monitoring for surface contamination has been a standard practice on work sites with radioactive materials since the 1950s, and a similar time span exists for dermal monitoring of pesticide applicators and harvesters. Only since the 1980s have these methods been applied to industrial and residential contamination with any regularity.

When used to determine the potential for dermal exposure, methods are often categorized as indirect or direct. Indirect methods involve the use of filters, gauze pads, or swabs to wipe surfaces; the use of instruments to “sniff” surfaces for volatile compounds; and the use of vacuum methods and adhesive tape to lift dust off surfaces. Direct methods measure exposure to the body and include the use of gauze, cellulose, or charcoal pads for dosimetry; analysis of clothing, skin wipes; washing the skin with solvent; and monitoring for skin color change and fluorescence.

Current sampling strategies emphasize air exposures and overlook the contribution of dermal exposures and surface contamination. Integration of surface and dermal monitoring techniques into sampling strategies is important so that a better estimation of exposures and therefore controls to protect against them are developed.

### 1 INTRODUCTION
Dermal studies can identify specific body areas that are being exposed, thus making sure the proper chemical protective clothing (CPC) is selected. They can also identify activities and work tasks within an operation that pose the highest risk of exposure, and assist in determining the proper types of controls needed. In some instances, dermal sampling will identify compounds to which workers are exposed that are not collected on air samples. For example, with polychlorinated biphenyls (PCBs), those with higher vapor pressures tend to volatilize whereas the heavier compounds remain on the skin. Therefore, the relative contributions of dermal and respiratory exposure routes can be assessed. Penetration of CPC and work clothing by contaminants can be determined, in part, by measuring contamination on the interior of garments and also on the skin that was to be protected. The effectiveness of decontamination procedures can also be assessed.

However, dermal absorption must take place in order for contact actually to produce an exposure. A central issue is determining when dermal exposure is likely to be the major route of entry compared with other routes of exposure. It is also important to determine what parts of the body are at greatest risk and to measure dose. The best program is often an integrated approach that uses surface and dermal sampling in conjunction with air and biological monitoring to assess not only the true dose an individual is receiving, but also the sources of exposure.

There is currently debate as to whether external measurement of dermal exposure or biological monitoring represents the best approach to determining exposure. Biological monitoring measurements of contaminants or their metabolites in body fluids (or breath) are considered better measurements of exposure in some cases because they represent an individual’s actual absorbed dose. However, the individual must have been exposed to and absorbed the contaminant in order to use these methods to determine dose.

Although in some cases biological monitoring is the only effective means of determining whether skin absorption is a significant concern, including detection of contaminants that do not have reliable sampling methods, it is ineffective for other compounds that are rapidly metabolized in the body. Some chemicals have poor biological warning properties or biological indicators of exposure and therefore are not good choices for biological monitoring. As an example, methylenediamine (MDA) easily enters the body through the skin and, once absorbed into the body, it is rapidly eliminated so that using a biological measurement such as the urine may not detect the apparent exposure. Therefore, the option of performing surface and dermal monitoring is important.

### 2 Skin Factors That Influence Permeability

The focus of skin exposure determinations is often the permeability characteristics of the contaminant, but other factors relating to the anatomy and the environment are also important. The importance of dermal exposure often depends on its contribution relative to other routes of exposure. Some factors increase the rate or extent of dermal absorption of a compound without impacting on pulmonary or oral uptake, which increases the relative contribution of the dermal pathway to total dose. Therefore, performing dermal exposure evaluations is much more complicated than just identifying those chemicals with high permeation rates.

The structure and condition of the skin and the specific characteristics of a contaminant determine whether a harmful exposure takes place. The skin surface area, anatomical site exposed, duration and frequency of exposure, contaminant absorption rate, fraction absorbed through the skin, concentration of the contaminant, its physical state, and the mixture in which it is contained are all important factors that affect dermal exposure. Individual and job-specific factors include skin hydration properties, such as visual stains on the skin or irritation that would make a person more likely to wash the skin promptly, thus limiting exposure.

Commonly called the acid mantle of the skin, a waxy type of mixture composed of sebum, breakdown products of keratin, and sweat coats the outer surface of the skin. It is believed that this coating protects against the penetration of water and water-soluble chemicals, but this protection is minimal and the layer is easily removed by soaps, solvents, and alkaline compounds.

The skin itself is composed of two layers: (1) the epidermis, a layer about 100 µm thick, and (2) the dermis, a layer about 500–3000 µm thick. The skin can absorb chemicals directly through the epidermal cells and through the hair and sweat follicles. The specific skin site that is exposed will also influence the degree of exposure. Certain areas such as the scrotum are more permeable than other areas of the body primarily owing to differences in stratum corneum thickness. Contaminants that permeate the skin can enter the systemic circulation via the capillaries in the dermis.

Important factors that influence the permeation of chemicals through the skin include the compound’s solubility, molecular size, concentration gradient on the skin, polarity, pH, and other permeability characteristics that are measured experimentally. Except for compounds...
with a molecular weight of 400 g mol$^{-1}$ and more, the molecular size and weight of a compound appear to have less of an effect on the rate or extent of percutaneous absorption than lipophilicity. The best penetrants are those that are soluble in both lipids and water, traversing the skin via both the lipid and aqueous pathways, whereas compounds that are largely soluble in one medium or the other are not as good at penetrating the skin.$^{(2)}$

### 3 SOURCES OF DERMAL EXPOSURE

Workers are exposed to a variety of physical states and concentrations of chemicals, including concentrated and dilute liquids, vapors in confined spaces, and contaminated soil and sludge on hazardous waste sites. Exposures do not have to be to large volumes of material to have a significant dermal effect. Many small exposures over a consistent period can build up over time, especially for chemicals that tend to have long half-lives in the body.

Dermal exposures to workers can be categorized as either primary or secondary.$^{(4)}$ Primary exposures occur as a result of direct involvement with the operation and include contact with process-generated contamination, equipment and materials used in the work area, or exposures generated as a result of work activities. The secondary exposures, which are more difficult to identify, occur when workers in turn contaminate surfaces remote from them.

The concern for dermal exposure does not end in the workplace. Environmental contaminants, such as lead and pesticides, can build up on surfaces such as carpets, walls, and counters inside homes and buildings regularly used by the community – schools, day care centers, and public office buildings – and may be associated with a number of different environmental media including water, soil, sediment, and consumer products. Contamination migrating from hazardous waste sites is also a concern. Workers wearing contaminated clothing may expose their families by close contact, contamination of furniture and rugs, contamination of other family clothing in the laundry, and contamination of family vehicles. Finally, hobbies and home industries can also contaminate residences.

The Adult Blood Lead Epidemiology and Surveillance (ABLES) program which is conducted in the USA draws on reports of high blood levels that medical laboratories transmit to health departments or other agencies in a number of states. It has been recognized that parents’ exposure in the workplace can be a source of exposure to the children at home, either through lead brought home on personal items or through exposing the children to the workplace. When elevated blood levels are identified in the parents, further information is gathered on children and other at-risk persons in the home.

### 4 SURFACE CONTAMINATION EVALUATIONS

There are a variety of reasons why surface contamination, especially removable surface contamination, may have to be sampled. Selection of compounds for surface monitoring depends on their ability to cause systemic toxicity via penetration of the skin, dermal irritation, sensitization, cancer, or oral toxicity. Whenever persistent contaminants are present on surfaces or in the air, there is a possibility that workers’ skin and clothing may become contaminated, and that these materials will be transported to surfaces in their personal vehicles and their homes, thus exposing their families. This is thought to be the primary reason why blood lead levels of household members residing in homes of workers with occupational lead exposures can be much higher than those of families of non-lead-exposed workers.

The variety of chemicals for which surface sampling can be conducted is large, although the most common groups are amines, metals and other toxic dusts, PCBs and tetrachlorodibenzodioxin (TCDD), and pesticides. Surface sampling for microorganisms is most commonly done to determine the potential for inhalation exposure either as a result of a heating, ventilating, and air conditioning system or by resuspension into the air after being disturbed on a surface.

Wipe sampling is useful for compounds that rapidly absorb through the skin as long as their physical characteristics are appropriate for this collection method. Surfaces that may be contacted by food or other materials that are ingested or placed in the mouth (chewing tobacco, gum cigarettes) may be wipe sampled (including hands and fingers) to identify contamination.$^{(4)}$ Wipe sampling methods have come under scrutiny recently with the result that the methodologies are producing more consistent results and, in at least one instance, the Lioy–Weisel–Wainman (LWW) Sampler may provide reliable quantitative results.

Chemicals for which wipe sampling is ineffective even though they can penetrate the skin include volatile solvents such as 1-butanol, because their evaporation from surfaces can be rapid and sampling will not provide adequate quantitation. Most gases such as bromine and boron trifluoride do not redeposit on surfaces, so sampling for them is ineffective; however, some gases such as arsine and stibine may revert to their metallic forms after contact with surfaces and remain. Owing to their volatile nature, most organic solvents are not suitable for wipes.

When accompanied by close observation of the operation in question, wipe sampling can help identify sources of contamination and poor work practices. Surface contamination may be readily apparent for colored compounds such as lead and cadmium pigments, but it may...
not be evident for surface deposition from lead fumes in a radiator shop or bumper (chromium) plating facility, or on dark and colored surfaces. In addition, the effectiveness of CPC such as gloves, aprons, and respirators in these situations can be evaluated by wipe sampling the inner surfaces of the protective gear (and protected skin).

It can be difficult to determine whether equipment or instruments are effectively decontaminated after they have been used in a contaminated area, such as on a hazardous waste site or for sampling of concentrated materials. Wipe and/or “sniff” sampling can be useful in determining whether these procedures are effective.

Surface deposits of the volatile type generally cannot be determined through conventional surface sampling methods and other investigatory methods are therefore necessary. In many cases, a field evaluation will depend on whether there is an instrument capable of detecting the contaminant of interest.

4.1 Standards for Wipe Samples

The simplest method for setting up a wipe sample standard is to compare qualitatively areas for relative contamination or use a zero acceptable criterion for areas that are supposed to be clean, such as eating areas and personal vehicles. Guidelines or standards have been developed for some chemicals. In California the United States Occupational Safety and Health Administration (USOSHA) has set a surface sampling standard for 4,4’-methylenebis(2-chloroaniline) (MBOCA). In the USA, the Department of Housing and Urban Development (HUD) has developed a standard for lead abatement methods and other investigatory methods are therefore necessary. In many cases, a field evaluation will depend on whether there is an instrument capable of detecting the contaminant of interest.

4.2 Surface Collection Methods

Surface sampling methods range from the use of hand pressure to move a filter against a surface, vacuuming, coupons, and mechanical devices designed to slide or roll for nonvolatile compounds to the use of direct-reading instruments to measure volatile surface contamination.

The most common surface sampling method used for chemicals is wipe sampling. For simplicity, the term wipe will be reserved for those methods using hand pressure to move media across a surface. Wipe sampling has also been termed swipe, smear, and smair sampling. Another method is the use of paper, cloth, tape, or microscope slides coated with an adhesive to press against the test surface to collect a sample of particles. Other collection media/methods include gauze, commercially available wet wipes, and vacuum cleaners.

Surface characteristics such as porosity or impermeability, smoothness or roughness, and the presence or absence of moisture have a marked effect on the potential for resuspension or release on contact of contaminants. Nonporous or impervious solid surfaces for United States Environmental Protection Agency (USEPA) purposes include metals, aluminum siding, and enameled or laminated surfaces. Porous surfaces include wood, concrete, asphalt, and plasterboard, and can allow contamination to permeate to a considerable depth. In these situations a core sample may be more appropriate than a wipe.

Adhesive tapes have been found to provide a better removal efficiency when taking samples from rough surfaces than wiping with filter papers. Waxes and polishes on surfaces can absorb contaminants and can be more difficult to decontaminate or to use for surface sample retrieval. In the case of a surface from which it is difficult to dislodge material, such as a carpet, vacuuming methods are better than wiping.

4.3 Sampling Media

Laboratory-grade filters are the most common media used. Generally there are two types of filters recommended by the USOSHA for collecting wipe samples. Glass fiber (GF) filters (37 mm, 1.0µm) are used for materials analyzed by high-performance liquid chromatography (HPLC) and often for substances analyzed by gas chromatography (GC). Methyl cellulose ester (MCE) air sampling filters or cellulose filtration-type filters are generally used for metals, and may be used for anything not analyzed by HPLC. Filters are fragile, and when using solvents extreme care must be used or they will be damaged.

Filter papers vary in their ability to absorb materials. A wide variety of commercially available materials have also been used for wipe sampling. Preweighing allows for the determination of concentrations (micrograms per gram) on media. However, tared wipe media can change characteristics in the field if not handled carefully. Moisture can be picked up or lost, and skin oils can contaminate media or add to the weight. Since MCE filters are very hygroscopic, they cannot be successfully tared for field use.

Media have been used with and without pre-extraction for many compounds, including lead and pesticides. A blank must be analyzed for background contamination prior to selecting the media, however, and along with

(continued overleaf)
the samples after collection. Media designed to be used as sterile bandages are often very clean anyway. While there have been some concerns about contamination in commercial media, these are considered to be minimal as long as the media are pretested for the contaminant to be sampled the first time they are used, and blanks of the media are included for analysis with the samples. Commercial premoistened hand wipes are frequently used for lead abatement sampling.

There is much debate over solvent selection. Solvents that increase the recovery of material from surfaces may not accurately mimic skin moisture. In this regard, a saline solution or water is considered the most appropriate solvent. Purity of solvents is important. Although they need not be of spectroscopic grade, they should be of sufficient purity not to contaminate the sample. Distilled or deionized water should be used rather than tap water. It is important that the same amount of solvent be used for each sample collection.

### 4.4 Sampling Strategies

The first step in developing a sampling strategy in which wipe sampling will be performed is to identify as closely as possible the type and expected concentration of contaminant(s). In any one survey it is best to be consistent and use media of the same size and shape. For comparing results from different surveys this is also best. The decision to use wipe sampling as the collection method in a survey should be made after evaluating its advantages and limitations. Wipe samples are inexpensive, fast, and simple to perform. They are useful as a screening tool, especially for trace elements. However, as a quantitative measurement they have several drawbacks, including operator bias and poor reproducibility. They are limited largely to trace elements and other inorganic analyses, and are sufficient for surface loading data (grams per square centimeter) but not for concentration (micrograms per gram) of the analyte in the dust. Wipes are not suited for sampling carpets or other absorbent materials, and the results may not reflect actual skin pickup.

In a single survey it is best to use the same size sampling area for all samples unless the surface or object to be sampled makes doing so impossible. If different surveys are to be compared, it is best once again to use the same sampling area for all chemicals. USOSHA methods use a 100-cm² sampling area, which is the most common, but any dimension can be used. HUD specifies a 1-ft² area for lead abatement sampling. Where different sized areas must be wiped, the size should be documented.

Templates are commonly used to assure consistency in the size of the area sampled. Both disposable and reusable templates can be used. If reusable, they must be decontaminated between samples, which is one reason why they are often constructed of galvanized or stainless steel rather than absorbent materials such as plastic.

Figure 1(a) shows the size of the template used by USOSHA and Figure 1(b) shows a template being used to take a sample inside of a tank. An alternative to using templates is to cut filter paper to the desired size of the sample, e.g. 10 x 10 cm, and place the paper over the exact surface to be sampled. The paper is then pressed evenly over the entire surface with a gloved hand. If several or all fingers are used, then equal pressure should be applied by all.

Samples can become contaminated from the hands of the samplers or, worse, sampling professionals might expose themselves to the contaminant. Therefore, clean gloves appropriate for protection against the contaminant being sampled should always be worn. A new set of gloves should be used with each individual sample to avoid contamination of the filter from the hand. Most often surface samples are collected on a one time only basis in order to make a recommendation to improve a program; however, regular repeat surveys to determine the effectiveness of cleaning programs or engineering controls will provide better assurance that they are effective.

Areas that are supposed to be clean, such as changing rooms and lunchrooms, are important to sample regularly. In addition, a number of obvious contamination buildup points should be visited and checked regularly: frequently used doorways, finger plates around essential controls, changing-room surfaces on the plant side of the changing facilities, and operative monitoring equipment in the plants.

If multiple samples are to be taken at a work site, one should prepare a rough sketch of the area(s) or room(s) to be wipe sampled along with the locations of key surfaces. Often air sampling locations are also included on the same diagram. Another sampling approach is to set-up a grid system and collect a specific number of samples inside each grid box. This strategy is commonly used in buildings suspected of widespread contamination. If the intent is to characterize and estimate the exposure over a large surface such as the tables in a lunchroom, collecting many individual samples for separate analysis and calculating the average of all the samples may provide a more useful estimate of the potential exposure. Alternatively, after several samples have been collected they can be composited for a single analysis. Compositing can make it easier to compare the sampling results of several dwellings.

In situations where the detection level for a contaminant is very low, several wipes may be collected, composited, and treated as a single sample. Samples for dioxins and dibenzofurans are often collected in this manner. In some instances where a large area must be sampled, compositing can be done to represent an entire surface such as a ceiling or each wall in a room.

4.5 Wipe Sampling

Various strategies for wiping exist (Table 2): wiping across the surface in either an “S” or a “Z” motion; wiping across horizontally or up and down; using a series of progressively decreasing circles or squares to fill up a circle or a square. To some degree the shape of the template will dictate the motion: A circular template would be done with a circular motion, and a square with either a square, horizontal, or vertical motion. Care should be taken not to rewipe any sections that have been wiped previously.

4.6 Lioy–Weisel–Wainman Quantitative Surface Sampler

A flat surface wipe sampler has been developed to quantitatively measure the concentration (micrograms per gram) and surface loading (micrograms per square centimeter) of dust on flat surfaces.\textsuperscript{30} The LWW wipe sampler consists of two sections, a template and a movable plate–filter retainer. It uses a template to map a specific area for the quantitative collection of dust and to control the movement of a collection plate. The moveable plate traces the rectangular opening within the template. The filter medium used to sample a surface is a ragged polyethylene drain disk material that is cut into rectangles of $3.8 \times 6.35$ cm. Self-closing forceps are used when handling the filters.

4.7 Adhesive Sampling

Cloth, tape, labels, and cellophane tape with adhesive backings have all been used for sample collection. The primary use of tape methods is to assess surface contamination of dusts, primarily in the asbestos industry, although the methodology was developed to collect dust for environmental and forensic purposes.\textsuperscript{37}

4.8 Vacuuming Methods

Vacuum methodologies have become an important aspect of surface sampling especially for collecting residential samples, and, therefore, the methodologies have been refined at least as much as those for wipe sampling, if not more. Vacuum methods most often involve the use of an elaborate apparatus many of which were developed under USEPA contracts. Vacuum methods are more effective for sampling carpets than filter wiping methods.

The advantages of vacuum methods include the collection of adequately sized samples providing enough material for detailed analyses, larger sample volumes allowing for more repetitions during sampling, providing better sample area coverage, the direct comparison of indoor dust concentrations to those in outdoor soil, and the ability to obtain surface dust loading and concentration data. Disadvantages can include the collection of dust that is inaccessible (and, therefore, nonrepresentative) for exposure, variable sampling efficiency between devices and for some surfaces, the requirement for sampling apparatus that is more costly than typical wipe media, and the need for more sampling time (including time to clean and decontaminate the devices between samples).

4.9 Personal Sampling Pump Method

The personal air sampling pump and filter cassette method has been standardized and is often referred to as the University of Cincinnati (DVM) method. The sampling pump is attached with Tygon tubing (3 mm internal diameter) to a 37 mm diameter three-stage cassette with a 0.8 µm MCE or other filter inside. Flow rates range from 2 to 3 L min⁻¹. In general, this method is limited to the collection of stable pesticides and metals. The most common method has a second piece of Tygon tubing attached to the front of the cassette as a suction head.

4.10 Colorimetric Surface Swypes

Surface “swypes” are sold by CLI Colorimetric Laboratories. They are absorbent pads impregnated with colorimetric reagent indicators to provide a visual determination of contamination on work surfaces and skin. A color indication within 2–3 min of placing the wipe in solvent is a positive result. The solvent is drawn up through the pad via capillary action, concentrating the contaminant in the colorimetric detection zone. A clear, plastic backing on the pad allows for the attachment of a handle and prevents the solution from contacting the user’s skin.

4.11 Dislodgeable Residues

Several methods are used to measure aerosol deposition: foam strips, tape, and surface vacuuming for dust or spray that has already settled. Tape samples are used primarily for surface asbestos contamination, but can also be used for other dusts. Vacuum methodologies have improved and, when used with prescribed methodologies, several devices can produce quantitative results. A standardized method for carpet samples has been developed by the American Society for Testing and Materials (ASTM). Occasionally a case can be made for collecting a bulk sample rather than wiping or vacuuming a surface, for example when a mechanical or manual device is used regularly to vacuum or sweep surfaces and the dust is derived from a floor or carpet. Dust has also been collected from carpet sweepers and used to represent surface contamination. Dislodgeable residues are collected using several methods, including the polyurethane foam (PUF) Roller, Dow Drag Sled, CFDA Roller, and, for foliage, coupons and leaf punches. Acids and bases (or alkalis) can be detected by their reaction with pH paper. Dislodgeable residue methods measure that portion of surface contamination likely to be removed by human contact. They are frequently used to sample carpets in residential studies. An example of these apparatus is the PUF Roller. The PUF Roller consists of a weighted roller fitted with a PUF cover that simulates the pressure applied to a surface by a crawling child weighing 9 kg (20 lb). The matrix of PUF is more similar to skin than the media used with other devices for dislodgeable residues.

4.12 Volatile Surface Contamination

When does a measurement for a volatile compound fall into the surface category rather than air sampling? Although this is a gray area, when a measurement is 1–12 in (2.5–30 cm) from a surface, it can be assumed that the source is the surface – unless there is a process that is actively generating the contaminant nearby. If measurement is in the breathing zone or in the middle of a room (general area) away from a contaminated surface, it can be categorized as air sampling rather than surface sampling. As is the case with other contaminants, surface sampling of volatile materials is usually done to determine if skin or clothing exposures are a concern. For many volatile contaminants, a general survey monitor with a photoionization detector (PID) or a flame ionization detector (FID) can be used. In this case it is important to remember that unless the instrument is calibrated with the contaminant in question, the results are all relative to the response of the instrument. In some instances screening for the presence of volatile materials on a surface can be useful to determine if further testing or decontamination is necessary.
5 DERMAL MONITORING

There are two types of methods for sampling dermal exposures: those that assess exposure indirectly by monitoring for surface contamination and those that directly assess the degree of contamination on the individual’s skin. Indirect methods, as discussed previously, include wipe sampling whereas direct methods are often experimental and have used cellulose, gauze, or charcoal pads, clothing for dosimetry, skin washes, and monitoring the skin for contaminants that fluoresce.

Pesticide manufacture, formulation, and field application were one of the first situations where dermal monitoring was performed, and the use of dermal monitoring has been expanded to virtually all areas involving pesticides, including field re-entry, harvesting, greenhouse work, office buildings, and residences. As a result, the methodologies that have been standardized for the use of dosimetry pads and whole-body dosimetry arose from pesticide monitoring.

Skin sampling can be done using methods that require laboratory analysis or using methods that produce either color changes upon exposure or fluorescence under ultraviolet (UV) light. Hands are the most common application for skin sampling methods when they are the primary source of exposure. Skin sampling is also useful to determine if cleaning methods are effectively removing skin contamination. Sampling under gloves and other CPC can identify previously unsuspected exposures and estimate the degree of protection achieved during actual field use.

Of the techniques that have been developed to monitor for dermal exposure, pad or patch dosimeters have been used the most. With pad monitors, contaminants are entrapped or absorbed by the cloth mesh of the multilayered materials of which the pads are composed. A common method involves placing absorbent pads at various points on a worker’s clothing and skin and exposing them for a carefully measured interval while the worker performs routine functions (Figure 2). The pads are removed and transported to a laboratory, where the contaminant is extracted and analyzed. The amount of contaminant that comes into contact with the skin is calculated using an anatomical model that allows for extrapolation of the small area represented by the pad to one or more body parts.

Pads can measure the effectiveness of personal clothing for protection against chemicals, estimate skin exposure, and determine which parts of the body receive the highest exposure. Pads fall into several categories. The most common have been developed to collect a contaminant in specific physical form: spray or dust. Multiuse pads designed to collect either dusts or sprays have also been developed. More recently, chemical dopants and other materials such as polyurethane have been used to collect specific chemicals or chemical families. α-Cellulose is commonly used for measuring sprays and surgical gauze is used for measuring dusts.

Pads have several advantages including their small size, portability, low cost, and passive sampling, which eliminates the need for pumps that require calibration and maintenance. The primary limitation of using absorbent pads is the assumption that exposures are uniform over various body parts. Since the pad technique collects a spot sample of the exposure to each body region, a potential source of error in using pads for sample collection is in the extrapolation from concentrations measured on a relatively small surface area compared to the entire body surface area.39

A variation of the absorbent pad method involves knitted cotton or other garments that cover the anatomical areas expected to have an exposure. These garments are then extracted in a laboratory for contaminants and the extract is analyzed. The most common method uses cotton gloves for collection and some studies have used long underwear.

Figure 2 Badges attached to worker using USEPA configuration. (Source: USEPA,38)
Clothing samples fall into two categories: items deliberately prepared and selected to be used as monitoring media and items of normal work clothing that are identified during surveys as highly likely to contain contaminants. These are then collected and either sacrificed for sampling or subjected to a nondestructive method such as wiping, sniffing, or vacuuming which is used as a qualitative determination of the presence of contaminants.

The whole-body dosimetry method is best used for preventive sampling, that is, to determine if there is significant skin exposure and to what areas of the body it is occurring. There are two methods: (1) using undergarments of cotton, long underwear tops and bottoms, and socks to assess the amount of material penetrating outer clothing; and (2) using disposable overgarments such as Tyvek® suits, which estimate exposure as if the skin were bare.

An alternative is to use portions of clothing to cut down on the bulk of material requiring analysis. This usually involves cutting away the most likely areas to show contamination either before monitoring or afterward. Cotton sleeves (covering the arm from the top of the arm to the wrists) and cotton leggings (covering the leg from the top part of the thigh to the ankle) washed before use have been used for sampling workers who were picking strawberries. In between these extreme lies the use of specific items of clothing, including gloves, T-shirts, and coveralls. If workers wear leather shoes it is possible for contamination to build up in them. In this case, foot exposure should also be assessed, which has been done by analyzing cotton socks.

A major obstacle is the lack of standard garments for sampling. In studies to date, garments have been selected for convenience rather than according to scientific criteria, and garment characteristics (fiber content, construction, finish, weight, thickness), of course, vary.

5.1 Interpretation of Dermal Sampling Results

With few exceptions, there are no standards related to dermal exposures; each situation must be handled on a case-by-case basis. The type of health effects caused, the contribution of skin absorption or ingestion to the total dose, and air sampling results (where appropriate) must be considered when evaluating sample results. The methods for calculating dermal exposure are fairly simplistic and frequently do not account for the use of protective clothing and its effectiveness. However, when measurements of dermal exposure are used to estimate absorbed dose, the amount of the contaminant penetrating clothing and estimates of dermal absorption data obtained in animal experiments should be incorporated into the result.

When interpreting results for dermal samples, it is generally assumed that 100% skin absorption has occurred unless the experimenter has enough information to adjust penetration using experimentally derived factors such as partition constants (e.g. the oil/water partition coefficient, \( \text{K}_{\text{o/w}} \)). However, direct dermal absorption from contact with a treated surface or deposited soil, dust, or liquids containing contaminants is difficult to assess.

5.2 Skin Sampling

When planning to sample the skin it is extremely important that the skin is cleansed before the day’s exposure begins and, following exposure, skin cleaning is even more important. Prior to surveys where wiping, swabbing, or washing will be used to sample the skin, subjects should be requested not to apply lotions or creams that day as they may interfere with the analysis or interact with the contaminant being sampled.

Sampling strategies most commonly attempt to identify whether a particular region of the body is being contaminated. Occasionally more than one area is sampled at a time, such as the forehead and hands. Most often skin samples are collected before lunch and at the end of a work shift or, in the case of community monitoring, on a one-time basis. However, another strategy that can be used in the workplace is to collect samples that reflect the exposure presented by specific tasks.

The neck is generally exposed and is not washed during the course of the day, hence it is a good sampling area. The forehead may have a higher exposure potential because chemical absorption may be increased due to the reduced skin thickness of this area. The USOSHA recommends that its compliance officers wipe only hands and fingers if doing skin wipes. Before any skin wipe is taken, the compliance officer must explain why the sample is necessary and ask the employee about any possible skin allergies to the chemicals in the sampling filter or media.

A problem with any skin sampling procedure is to find a solvent that will provide adequate removal of residues without causing injury to the skin or increased absorption of a contaminant. Most often the solvent used to sample direct skin is water. Solvents should be selected that are not irritating, do not cause drying or cracking of the skin, and are not readily absorbed by the skin. In addition, they should not facilitate skin penetration of the material being sampled.

Commonly used solvents to rinse contaminated workers’ hands are 95% ethanol, 10% 2-propanol, acetone, distilled water, or water containing detergent, or some combination of these three materials such as 50:50 ethanol–water.
Wiping methods for skin use the same types of media as are used for surfaces, such as filters, gauze, and commercial premoistened wipes. Given the concerns regarding solvent selection in the previous section, the simplest option is to wipe the skin with a dry filter. In some instances the skin will be moist with perspiration and the use of a solvent will only dilute the sample. Depending on the compounds for which analysis will be performed, perspiration can present problems.

Similar to surface wipes, skin wipes should be done on equal-sized areas so that comparisons can be made not only of different areas on the same individual, but also of different individuals. One way to determine if the source of a contaminant on skin is related to the immediate environment is to wipe control subjects (who are in known contaminant-free environment) and compare these to skin samples of exposed persons. There may be a limitation to the number of times a hand can be wiped or washed per day because skin moisture and oils can be depleted.

A disadvantage of wipe methods to detect semivolatile mixtures such as polycyclic aromatic hydrocarbons (PAHs) is their inability to collect the most volatile fraction. Skin wipes can be collected using Whatman Smear Tabs (No. 50). The wipe samples are analyzed using the same procedure as that used on the filter wipes for surface contamination. A variety of premoistened commercial materials have been used to perform skin wipes. Hand and face wipes for lead exposure have been performed with a commercially available paper towel premoistened with benzalkonium and alcohol. The method that is frequently used to perform hand wipes, especially for lead, utilizes premoistened commercial baby wipes and is as follows. The first wipe in the package is discarded. The subject is asked to pull the second wipe. Hand and face wipes are usually composted.

The USEPA recommends skin washing for hand exposure estimations. Skin washing is considered most appropriate for chemicals that have low rates of dermal absorption. Skin washing has been used for the hand, wrist, arm, foot, and ankle, but most commonly the hands are washed. Some studies have rinsed the entire arm (wrist bone to shoulder), the torso, and portions of the legs, but swabs are usually used for larger parts of the body.

Rinsing techniques may be more representative of actual exposure than surface (pad, cotton glove) methods because the skin is subjected to more variables such as sweating and changes in body temperature. However, the effectiveness of this method is severely limited by the rapid rate at which the skin absorbs and retains certain compounds, such as organophosphates. Therefore, skin rinsing may underestimate the potential dose, because only the unabsorbed or slowly absorbed fractions of a contaminant may be collected.

The bag rinse procedure is the most common rinsing method and involves the use of polyethylene bags containing a suitable solvent, such as distilled water, for washing the contaminant from the hands. The most common intervals to select for rinse samples are morning break, lunch, afternoon break, and after work. Sometimes a sample is collected before the start of work to determine if there is residual contamination. Bags are selected that are sturdy enough to hold 200 mL of solvent. The bag rinse may be more effective than the swab method for removing hand contamination. Three sequential rinses have been shown to be optimum to assure that most of the contaminant has been removed from each hand. For analysis, rinses of the same hand are usually composited.

Hand washes can be performed as simply as releasing 250 mL of distilled water or other solvent from a separating funnel or other container held over the hands, and collecting it in a stainless-steel bowl. The wash water is transferred to glass jars that were covered and sealed. Washing the hands in a stream of solvent or in a basin containing solvent is faster than shaking the hands in plastic bags containing solvent, but is not as standardized or as convenient as the bag rinse. Sunflower oil has been used to wash hands for PAH exposure. This may also be suitable to collect other oil-soluble, sticky materials which will not rinse off easily with a solvent. Hand rinse solutions can be quantitatively transferred to volumetrics and diluted to a 100 mL volume for analysis.

Preweighed adhesive labels have been used to sample a standard area on the palms of children for lead exposure from contaminated soil. Tape has been used to collect fibers directly from skin when employees in a data-processing computer room were complaining of itching and localized rashes.

5.3 Direct-reading Methods

Direct-reading methods are available for skin monitoring for PAHs, amines, and metals. At the simplest, monitoring can be examination of a worker’s skin for obvious discoloration since certain compounds such as methylenedianiline will cause this effect. The best known direct-reading method is fluorescence, which has been used to identify dermal contamination in two situations: when compounds such as PAHs possess a natural fluorescence and when fluorescent compounds have been deliberately added to chemicals so that their contamination can be visibly traced. UV light is used to visualize the contamination in both cases. The technique consists
of scanning the body of a worker with a hand-held UV lamp and examining the fluorescence in a dark room. Photographs are often used to permit more careful study later and comparisons among subjects.

Video imaging has been integrated into studies using fluorescent tracers, and although it is not yet widely used, it may be a primary method in the future since air sampling studies are also incorporating this technique. An important advantage of the technique is its ability to provide an assessment of the affected body areas.

Although UV light has been used in several plants to detect skin contamination, there is still concern about the risk of skin sensitization and carcinogenic effects.

5.4 Pad Dosimetry Methods

Dermal sampling using small pads or patches attached to various areas of the skin or clothing is one of the most standardized methods for collecting chemicals. Pad samplers of cellulose materials such as filter paper and multilayered gauze are appropriate for sampling contaminants with low vapor pressure, when exposure is the result of airborne mists or dusts. For volatile materials, pads containing charcoal have been developed, and for certain semivolatile materials, polypropylene pads have been used. Although they are not as well tested as the cellulose pads, their use is promising because they may provide for greater collection efficiency and a broader number of compounds for sampling. Other variations include the use of multiple materials and adding chemical dopants to enhance collection.

Pads must be absorbent enough to retain all the liquid that contacts them or, if used for collecting dusts or dried residues, must be porous enough to collect these materials. The pads must be strong enough to hold up under the abuse that they will receive in the field. They must not contain additives such as sizing that will interfere with the chemical analysis of the extracted chemicals. Additives can usually be removed by pre-extraction of the pads; however, some interfering compounds cannot be adequately removed to allow analysis of low levels of contaminants. The following are variables in pad use: size, type of medium, combinations of media, backing(s), number of layers, pre-extracted versus not extracted, holder, means of attachment, number of pads used for monitoring, sampling locations, overlapping versus adjacent pads, sampling period, and whether combined or analyzed separately.

The USEPA recommends that pads be constructed from papermaking pulp or a similar material, approximately 1 mm thick, which is commonly called α-cellulose, especially if sprays are being collected. It resembles blotter paper. Gauze pads are recommended for dust collection. They can be assembled from individually cut layers of material or used as off-the-shelf medical supplies, such as surgical dressings or sponges. The composition of a typical gauze pad for dermal sampling is layers (often 8, 9, 16, or 32) of surficial gauze with an impervious backing. Soft polypropylene has been used as an adsorbing material for PAHs and may also be useful for sampling other semivolatile materials. Gauze pads have been doped with glycerin to enhance the collection of MBOCA.

The size of pads can vary, although commonly used sizes are 3 × 3 in, 4 × 4 in, and 2 × 2 in (1 in = 2.54 cm). Different sized pads may be used for monitoring different sized body parts. The purpose of backings is to prohibit contamination of pads by skin oils and perspiration from beneath the dosimeter. Glassine (weighing) paper, polyethylene plastic (4–10 mL), filter paper, brown wrapping paper, and aluminum foil are commonly used as backings. A multiuse pad for situations where both dusts and sprays are being generated either at the same time or sequentially, such as when pesticides are mixed and then applied by the same person, consists of one or more layers of filter paper covered with multiple layers of gauze, e.g. eight-ply surgical gauze stapled to a double layer of filter paper with a backing of manila poster paper. The filter paper readily absorbs liquid while the gauze collects impinging dry residues and the poster paper provides extra mechanical strength.

To hold the pad together during sampling there are a number of options, ranging from a simple staple in the center to surrounding it with tape or placing the pad inside a specially made holder. Holders have been made by cutting a hole in one side of a glassine paper envelope. The finished pad should be bound so that the maximum sampling area is exposed. A protocol should be developed prior to the start of the study that sets the criteria for collecting samples taking into account the goals of the survey. In order to eliminate the contribution of previous contamination from workers’ clothing to a new sampling day, a standardized set of laundered clothing can be issued to all subjects at the start of each day’s operation. At the end of the exposure period the clothing is collected along with the pad samplers. When pads are used on top of disposable clothing, this clothing is also replaced between applications. The number of workers selected to be sampled and, where multiple sites are involved, the number of sites selected to develop a representative sample must also be decided. In general, it is best to monitor as many different individuals as practicable at any given time.

There are four basic strategies for locating pad dosimeters: (1) measuring dermal exposure or deposition on the body due to the environment only, in which case dosimeters are placed outside the work clothing only; (2) measuring dermal dose to skin, in which
case dosimeters are placed on the skin under the clothing; (3) measuring both skin and work clothing exposure, which also allows one to measure the protection afforded certain clothing; and (4) measuring the degree of protection provided by CPC, in which case sometimes three layers of pads are used.

As for standardized methods, the USEPA has two different pad location scenarios: one for sampling workers not wearing impervious CPC and another for when CPC is worn. The World Health Organization (WHO) and the National Agricultural Chemicals Association (NACA) have also developed protocols (Table 3). When only work clothing and no impervious CPC is worn, the USEPA recommends that at least 10 dermal pads be attached at the following locations: in front of the legs just below the knees, in front of the thighs, at the back of the forearms, on top of the shoulders, at the back of the neck at the edge of the collar, and on the upper chest near the jugular notch. If a CPC suit is being worn, only six pads are attached. The most common placement is to offset the interior pad so that it is right next to the exterior pad on top of the clothing so that both pads sample similar exposures. These extra pads should be attached to areas of the body that are expected to receive the highest exposure.

If pads are placed both inside and outside normal work clothing, the ability of the fabric to protect against the contaminant can be determined by comparing the outer and inner monitored values. It is important to note that the workers’ shirts and trousers are often constructed of different materials and, therefore, comparisons of penetration between workers may be difficult. While the standardized methods for pad placement are useful, the specific needs of the survey may require other variations. The final selection of sites will depend on the potential for exposure during a specific activity. If exposure is expected to be limited to the arms, and it has been demonstrated in prior studies of the same task, then there is no benefit in sampling the head, chest, back, etc.

There are a variety of ways to attach pads to clothing. Some studies have utilized specially designed harnesses or lightweight vests fitted with open-front pockets to hold the shoulder, chest, and back pads in position. Chest pads have also been placed inside shirt pockets. When pads are placed under garments, various approaches are: to tape the pad to the skin under the garment, pin the pad under the same clothing to which the outer pad is attached, or pin or tape the pad to a T-shirt underneath the clothing. Surgical tape used to attach pads to the skin is generally nonirritating to perspiring skin and tolerable by the wearer.

Monitoring media should be changed during some natural break in the worker’s schedule. Pad replacement is done when different tasks are to be monitored, when heavy buildup is suspected, or when gathering information on morning versus afternoon exposures.

Attaching pads to disposable jackets, coveralls, and hats minimizes the time required for changeovers for resampling. Another way to speed up pad exchange is to staple pads to the outside of fresh white cotton T-shirts and put the shirts over the subject’s work clothing at the beginning of the exposure period.

A photograph of each worker in sampling garb is useful for estimating the amount of skin exposed, type of work clothing worn, and CPC worn. Extensive notes (Figure 3) should be taken during sampling including temperature, humidity, wind velocity and direction, duration of sampling, type, concentration, and amount of chemicals present, type of equipment used, and any other parameters relevant to the process. Typical observations often made of the individuals being sampled are physical characteristics (sex, age, weight, height, and body surface) and individual productivity. It has been suggested that age correlates positively with productivity, possibly because older workers are more experienced and motivated.

At the end of the sampling period, the pads are carefully removed from the worker. Care should be taken not to touch the sampling portion of the absorbent pad. Samples can be handled by their outside perimeters, or clean latex gloves worn or forceps used to remove them. When feasible, fold the dosimeter onto itself before sliding the pad into its original prelabeled plastic bag, and seal or place two dosimeters into the bag face-to-face if they

5.5 Clothing for Dosimetry

Whole items of clothing used as samplers eliminate the need to extrapolate an exposure from a smaller collecting device such as a pad over the body surface. Clothing items are usually prepared and placed on the subject for the specific purpose of sampling, although workers’ personal clothing has also been collected for analysis. Gloves have been used for the hands, short-sleeved undershirts for the upper part of the body, socks for the feet, and the tops of socks for both ankles and wrists. Work clothing has also been analyzed after laundering to determine the effectiveness of laundering. Whole items of clothing usually contain material that must be extracted prior to use and require large amounts of solvent for extraction of contamination.

It is very difficult to change clothing or underclothing after each exposure period without interfering with the work pace. Also, it is nearly impossible to remove these garments without contaminating them with residues from other areas of the body, especially those on the workers’ hands and hair, unless special precautions are taken. Occasionally a garment may have to be cut off the subject in order to avoid its contamination by some part of the body. T-shirts fall into this category. Clean, disposable gloves should always be worn when removing and handling items of clothing used for sampling. Clothing used as samplers has the advantage of decreasing exposure to the skin; however, it can saturate and, once contaminated, become a source of continuing exposure. Lastly, covering contamination already present on the hands or body with dosimeter clothing may result in an increased exposure of the test subjects due to occlusion, so hygiene is important.

Absorbent gloves are a popular method for measuring contaminants contacting the hands. Two types of lightweight absorbent gloves are used most frequently: white 100% cotton gloves which are typically white cotton twill work gloves with knit wristlets and seamless palms, and white nylon gloves similar to those used for fruit picking. Nylon gloves are lint-free and some studies have found them easier to extract than cotton gloves. Leather gloves have been used for sampling, especially if they were typically used in a specific job.

Prior to use, gloves are usually prepared in a manner similar to dosimetry pads to remove interferents. They may be laundered one or more times with detergent, bleached, and then extracted with a solvent such as acetone or a solvent blend (hexane–acetone) one or more times depending on the level of analytical detection required. The amount of time each subject wears the gloves should be recorded. Gloves should be replaced whenever obvious staining or moisture has soaked into them.

As with dosimetry pads, the gloves can be composited or extracted individually for analysis. Sometimes only sections are cut from the back and palm of gloves or they can also be cut into pieces.

Gloves are often used when hand rinses are not acceptable. Lightweight absorbent gloves also provide several advantages over rinsing or swabbing for the assessment of hand exposure. It is easy to exchange gloves in between monitoring periods. Absorbent gloves are the only method for monitoring the hands that will collect residues that would otherwise be absorbed into the skin during the exposure period, although if the exposure period is too long or concentrations are too great a breakthrough may occur.

The primary advantages of using gloves are ease of use and the fact that the hands represent one of the most highly exposed dermal areas. The contamination over the entire surface of the hand is collected, so there is

are to be analyzed as one sample. Place all the bags from a single test subject in a sealed container such as a wide-mouthed jar or another plastic bag.

There are two different ways of analyzing pads. One method is to combine pads from opposite sides of the body prior to extraction. For example, both forearms would be combined as well as both legs. However, if exposure values from particular pads are needed for calculations, these pads must be extracted individually. Calculations are generally performed in order to extrapolate the results of pads over the specific anatomical areas of the body their sampling locations represent.
no need to estimate using extrapolation methods. The use of gloves may have certain disadvantages, however. Cotton and nylon gloves have absorption characteristics that differ from those of the skin. They can get in the way and impede work where high dexterity is required. The wide variety of hand shapes found in the population (palm widths, finger lengths) makes it difficult to get a smooth fit in many instances because the sizes of gloves are limited. Gloves may absorb more material than would be retained by the skin, thus overestimating hand exposure. Even smooth-surfaced nylon gloves may retain several times more residue than would have adhered to flesh. Gloves also contain foreign materials such as sizing that may be difficult to remove by pre-extraction and may interfere with chemical analysis of low levels of contaminants. This problem can be reduced by pre-extraction of gloves with an appropriate solvent.

Cotton or nylon socks are used to measure the amount of contaminant that enters the shoes in a method similar to using gloves for measuring hand exposure. Socks with the feet cut out have been used for measuring exposure around the forearms, lower legs, and ankles. Perspiration may be a greater concern when using socks to sample than when using gloves because boots will trap moisture. Therefore, if the boot material is suitable, rinses of the boot interiors may be more useful than monitoring using socks. Many parts of shoes have been wiped or “sniffed” with a direct-reading instrument, depending on the contaminant.

Paper caps have been used to measure head (scalp) exposure. Disposable paper respirators have been used to estimate facial exposures and will provide an estimate of contamination to the nose, chin, and cheeks. An advantage of this method is that the shape of these masks results in their touching the face only around the edges where the face seal is made. This eliminates the problem with sweating and picking up potentially eliminated contaminants that may have been stored in the skin, and also that of getting the sampling media damp. A disadvantage is that the mask surface area is much larger than the portion of the face that is covered, so estimates of the actual skin surface area being sampled may be difficult. Respirators can also be used to collect samples representing inhalation exposure.

Fabric tights (footless, white) made of 54% cotton, 36% polyester, and 10% spandex have been used for monitoring dermal exposure to carpet residue produced by indoor pesticide foggers. Blue jeans have been analyzed for exposure to pesticides (ethyl and methyl parathion) during field re-entry. All jeans were purchased from the same manufacturer. Prior to use the jeans were laundered twice. Analysis was done by washing the jeans separately three times in hexane, soaking them for 10 min during each wash. The extracts were combined and concentrated or diluted, as required, for GC analysis.

Short-sleeved T-shirts have been used to measure the amount of a contaminant that penetrates through outer work clothing, both ordinary work garb and CPC. All T-shirts were from the same manufacturer. Prior to use the T-shirts were laundered twice. Analysis was similar to that for blue jeans as described above. Underpants may be useful for studying exposures to compounds known to produce scrotal cancer, such as PAHs.

5.6 Whole-body Monitoring

Overalls and coveralls can be used along with gloves to approximate the total body exposure. As with other clothing, there is the option to either analyze a worker’s existing clothing or to purchase and prepare clothing to use specifically for sampling. One application in which it is best to use the worker’s personal clothing is when there is a question as to whether contamination is remaining in the clothing.

The current trend is to use long underwear, sometimes called a union suit, or disposable CPC body suits such as Tyvek®. When worn under regular clothing, a body suit covers the entire trunk and the extremities; alternatively, disposables can be worn over regular clothing. When used as underwear, the suits are often worn for 4 h and then collected. Removal must be done carefully so as not to disturb collected material. After removal the underwear is often placed in Zip-Loc™ bags and stored on dry ice until processing. Clothing can be cut up in order to identify exposures to specific parts of the body. In some instances after observing workers a decision is made to analyze only portions of the long underwear such as arms and legs.

A procedure for using disposable body suits has been developed by the WHO. When using disposable coveralls to perform whole-body dosimetry the material should be checked first to determine its ability to collect the contaminant of interest. For example, some compounds such as Ethazol™ will readily penetrate Tyvek®.

Clothing dosimetry is currently the only technique that can be used to measure contamination to the total body surface without having to use extrapolation from a smaller sampling area. A disadvantage of this method is the potential for heat stress to workers due to the additional layer of clothing. However, concerns still exist as to how accurately the residues picked up by the disposable suits or long underwear reflect the ability of the skin to collect and retain contaminants.
6 CONCLUSIONS

Current sampling strategies emphasize inhalation exposures and overlook the contribution of dermal exposures and surface contamination. Although in some cases biological monitoring is the only effective means of determining whether skin absorption is a significant concern, it is ineffective for other compounds that are rapidly metabolized in the body. Integration of surface and dermal monitoring techniques into sampling strategies will provide a better estimation of actual exposures and therefore ensure that appropriate controls are developed. The best program is often an integrated approach that uses surface and dermal sampling in conjunction with air and biological monitoring to assess not only the true dose an individual is receiving, but also the sources of exposure.

Nucleic Acids Structure and Mapping: Introduction

Cassandra L. Smith
Boston University, Boston, USA

The articles presented in the section, Nucleic Acids Structure and Mapping, illustrate the breadth of basic and applied research in this area today. The subjects range from basic chemical characteristics and three-dimensional structures of nucleic acids, to new high and low resolution analytical methods. Several articles illustrate the increasing interest in nucleic acids as biomaterials. The basics of many of these subjects have been discussed in my recently published textbook. Information relative to nucleic acids may also be found in other sections (e.g., Biomedical Spectroscopy, Biomolecules Analysis, Mass Spectrometry, Nuclear Magnetic Resonance, and Electron Spin Resonance Spectroscopy, and Scanning Probe Microscopy, Industrial Applications of). Some articles in other sections relevant to nucleic acids are indicated below along with pointers to subjects covered in this section.

Nucleic acids were first isolated by Friedrich Miescher in the late 1800s from salmon sperm. Until the 1940s, DNA was believed to be a structural component within cells. In 1950, Chargoff noted that although the mole ratios of each of the bases in DNA from different organisms varied, while the G/C and T/A ratios were 1.

From 1944 to 1952, a series of experiments by Oswald Avery, Colin MacLeod and Maclyn McCarty and by Alfred Hershey and Martha Chase, using Escherichia coli, established DNA as the genetic material. In 1953, the X-ray diffraction experiments of Rosalind Franklin allowed James Watson and Francis Crick to described the canonical helical structure of double-stranded DNA. The ability to understand DNA function using the Watson–Crick model led to an explosion of functional studies on nucleic acids. These studies were aided by the ability to analyze and manipulate DNA first in model systems taking advantage of their genetic systems and then with DNA from virtually any organism using only a relatively few recombinant DNA methods.

Despite the long history and interest on nucleic acid research, and the existence of only five different monomers (A, T, U, C and G), today it is not possible to predict the precise three-dimensional structure of a non-canonical DNA structure (DNA Molecules, Properties and Detection of Single; DNA Probes; DNA Structures of Biological Relevance, Studies of Unusual Sequences; and RNA Tertiary Structure). This situation is in contrast to the progress that has been made in understanding and predicting the structure of proteins composed of 22 different amino acid monomers. Furthermore, there is an increasing renewed interest in understanding basic DNA chemistry promoted by research on peptide DNA (PNA and Its Applications) as well as other phosphodiester or base modified DNAs, and the proliferation of research on the selection and construction of nucleic acids with novel enzymatic activities or structural properties (Structural Analysis of Ribozymes and Aptamers). In addition, the search for cheaper and faster DNA sequencing and mapping methods (Sequencing Strategies and Tactics in DNA and RNA Analysis), prompted by the Human Genome Project, has also refocused attention on DNA fundamentals.

Hence, the first series of articles in this section are on basic chemical characteristics (Nucleic Acid Structural Energetics) and non-canonical nucleic acid structures and the methods that are used to analyze them. This includes X-ray diffraction methods (X-ray Structures of Nucleic Acids), nuclear magnetic resonance (Nuclear Magnetic Resonance and Nucleic Acid Structures), chemical (Polycyclic Aromatic Compounds Mapping), Raman Spectroscopy in Analysis of Biomolecules in the Biomolecules Analysis section, and enzymatic footprinting (Structural Analysis of Ribozymes) as well as some well established methods such as electrophoresis.

One obvious omission in this section is research using nucleic acids to build specific 3-dimensional homogenous and heterogenous molecular structures. Nucleic acids (and peptides) are versatile tools for building molecular structures and have the advantage of providing fast prototyping since virtually any nucleic acid sequence can be rapidly and easily synthesized.

There are relatively few well-established methods that have been available to a large number of researchers for analyzing DNA. These include conventional DNA sequencing, hybridization (Sequencing and Fingerprinting DNA by Hybridization with Oligonucleotide Probes), the polymerase chain reaction (Polymerase Chain Reaction and Other Amplification Systems), and electrophoresis. Many of the basic methods have made their way into clinical (in Clinical Chemistry section Nucleic Acid Analysis in Clinical Chemistry and forensics (in Forensic section Polymerase Chain Reaction in the Forensic Analysis of DNA) applications. Mass spectrometry (Mass Spectrometry of Nucleic Acids and Mass Spectrometry in Structural Biology in the Biomolecules Analysis section) promises to make a major impact in the areas traditionally served by these technologies.
Refinements in hybridization experiments have led to the production of DNA chips (in Clinical Chemistry section DNA Arrays: Preparation and Application) and sequencing by hybridization strategies (Sequencing and Fingerprinting DNA by Hybridization with Oligonucleotide Probes) for DNA analysis. DNA hybridization can also form the basis of biosensors (Fluorescence-based Biosensors in Biomolecules Analysis section).

DNA chip or SBH experiments can be viewed either as DNA sequence fractionations (i.e. sorting by hybridization) or as DNA fingerprinting experiments. Some DNA fingerprinting methods including indexing sequencing methods that developed from the idea of accumulated sequence around restriction enzyme cleaved sites (sequence tagged restriction sites (STARs)). A DNA fingerprinting method focused on restriction enzyme cleavage sites (Restriction Landmark Genomic and cDNA Scanning) is presented here.

Recent developments in fast, high resolution DNA fractionation methods (e.g. Capillary Electrophoresis of Nucleic Acids) are also presented. A number of low resolution methods of analysis are presented, including the analysis of human chromosomes by fluorescent in situ hybridization (Fluorescence In Situ Hybridization) and electron tomography (Electron Tomography of Chromosome Structure and Single Molecule Detection and Characterization). One new low resolution method that directly observes and measures DNA length microscopically is being used to create genomic restriction maps (Optical Mapping in Genomic Analysis). An important omission in this section is direct DNA visualization using atomic force microscopy (ATM). Articles in other Encyclopedia sections include Atomic Force Microscopy in Analysis of Polymers, and the entire section entitled Surfaces. Some recent reviews on DNA have been published.

Other articles in this section discuss radiation hybrid mapping (Radiation Hybrid Mapping) of and the construction and mapping of libraries composed of bacterial artificial chromosomes (Genome Physical Mapping Using BACS) or other cloned sequences. A cheap and easy alternative to these low resolution mapping approaches is one we have developed called cloneless libraries. In the cloneless library approach, genomic restriction fragments purified from pulsed field gel electrophoresis fractionations are used in place of cloned sequence. This approach is cheap, and easy, and has the advantage that a cloneless library can easily be generated from any DNA source.

This section of the Encyclopedia closes with a review of comparative genomic methods focused on differential display and subtractive hybridization (Comparative Genomics: Differential Display and Subtractive Hybridization). These comparative methods are accessible to the largest number of people. This article serves to remind the reader that it is comparative genomics that will synthesize new biological information.

It should be apparent that the articles presented in this section do not exhaustively cover current research on nucleic acids. Rather, they are representative of a wide spectrum of possibilities. It is hoped that a reader will be able to initiate studies in specific areas with the articles presented here but also recognize that this field is rapidly changing and so should also be prepared to investigate other areas not reviewed in this section.

Aptamers

William James
University of Oxford, Oxford, UK

1 INTRODUCTION

Aptamers range in size from approximately 6 to 40 kDa and sometimes have complex three-dimensional structures, produced by a combination of Watson–Crick and non-canonical intramolecular interactions. They bind to their targets with $K_D$ typically in the low nanomolar range and can distinguish enantiomers of small molecules or minor sequence variants of macromolecules with frequently several orders of magnitude $K_D$ ratio. They are typically composed of RNA, single-stranded DNA or a combination of these with non-natural nucleotides.

Aptamers are isolated from extremely complex libraries of nucleic acids, generated by combinatorial chemistry, by an iterative process of adsorption, recovery and reamplification. Additional sequence variation can be introduced at each cycle and the process becomes an in vitro paradigm of Darwinian evolution. After sufficient enrichment, aptamers can be cloned and studied as homogeneous sequence populations.

Aptamers can be used to analyze the natural processes of nucleic acid–protein recognition, to generate inhibitors of enzymes, hormones and toxins with potentially pharmacological uses, to detect the presence of target molecules in complex mixtures and to generate lead compounds for medicinal chemistry. Their advantages over alternative approaches include the relatively simple techniques and apparatus required for their isolation, the number of alternative molecules that can be screened (routinely of the order of $10^{15}$) and their chemical simplicity. Disadvantages of aptamers include their pleiomorphism, their high molecular mass and the restricted range of target sites that appear to be suitable.

2 IN VITRO EVOLUTION OF NUCLEIC ACID LIGANDS

2.1 Outline of Process

Aptamers are ligands derived by a process of combinatorial chemistry, in which the desired property is identified by affinity chromatography and encoded genetically. The process is illustrated in Figure 1 and described below.

2.1.1 Library Synthesis and Complexity

Combinatorial chemistry is the production of a very large number of different molecules by the repeated
use of a limited range of synthetic steps. It takes many forms, outside the scope of this article, but was inspired by the sequential, solid-phase synthesis of oligopeptides and oligonucleotides (oligos: Combinatorial Chemistry Libraries, Analysis of). An oligo of defined sequence is commonly synthesized on a solid support by a cycle of deprotection of the acceptor end of the growing chain and its derivitization by using an excess of the next activated monomer in the mobile phase. By modifying this process so that the activated monomer is a mixture, rather than a single species, oligos of randomized sequence may be readily obtained. For sequences of randomized length \( N \) and \( y \) alternative monomers at each position, a library of oligos of diversity \( y^N \) can, in principle, be synthesized. For example, a nucleic acid library of randomized length 40 has a maximum theoretical diversity of \( 4^{40} = 1.2 \times 10^{24} \). The theoretical diversity, otherwise known as sequence space, of such a library will often exceed by many orders of magnitude the number of molecules that can be handled in practice. Convenience and expense generally restrict the initial library to a sample of in the region of \( 10^{13} - 10^{15} \) molecules taken, presumably randomly, from the larger sequence space.

2.1.2 Selection of the Desired Property

The desired property is, typically, the ability to bind to a molecule of interest. Depending on the anticipated application, the desired binding properties may be a fast association rate, slow dissociation rate, high affinity, low affinity to closely related molecules, or a combination of these. This property will be a function of the three-dimensional structure of the folded nucleic acid and will be a combination of its van der Waals surface contacts, hydrogen bonds, stacking interactions and other non-covalent bonds that can form between the aptamer and its target. It is a necessary assumption that, to a reasonable approximation, the three-dimensional structure of an aptamer is uniquely determined by the sequence of its bases. These assumptions will be explored below.

By mixing the solution-phase library with the target molecule and subsequently retrieving the target and removing unbound or loosely bound nucleic acids, the few nucleic acids that have the desired property can be recovered from the library. This partitioning step is a form of affinity chromatography and the methodology can be varied depending on the nature of the target and the exact property desired. This will be discussed in detail below. The selection step differs from screening methods used in other branches of combinatorial chemistry because of the numbers of candidate molecules that can be reviewed at one time. Conventional libraries of potential drugs may consist of the order of \( 10^6 \) molecules, which can be screened for activity by robotic means in a few months. Combinatorial libraries of greater than about \( 10^5 \) are impractical to screen by conventional, iterative methods, as vanishingly few molecules of each species would be present in each assay. Perhaps the most sensitive methods involve affinity partitioning followed by mass spectrometry (MS).\(^2\)
2.1.3 Genetic Encoding

In contrast to other forms of combinatorial chemistry, where a variety of methods have been devised to encode the structure of each agent, or at least its synthetic recipe, in the solid-phase support, aptamers contain within themselves the genetic code for their own amplification and synthesis. Nucleic acid polymerase enzymes are used to convert the target-bound aptamer, if it was based on RNA, into DNA, to amplify the copy number exponentially (by a factor of at least $10^{10}$) and, again if the aptamer is RNA, to transcribe the amplified DNA template back into RNA.

2.1.4 Enrichment and Evolution

Because the affinity-based partitioning methods are imperfect, the cycle of partitioning and amplification is normally repeated 6–12 times, sometimes more, before molecules of the desired property predominate in the population of nucleic acids. The process, as described above, represents a reduction in sequence diversity from the initial sample of sequence space (e.g. $10^{15}$ out of a space of $10^{24}$) to a population of the order of typically 10 distinct sequences that show appreciable binding to the target. In addition, however, the error-prone nature of the enzymes used to amplify the selected sequences leads to the introduction of mutations that effectively allow the procedure to sample a greater proportion of the sequence space than was initially sampled. This leads to the appearance of clearly related but evolutionary divergent sequences within the final aptamer population, in a process akin to Darwinian evolution by natural selection.

2.2 History of Discovery and Development

While experiments involving the isolation of nucleic acids from artificial libraries on the basis of their biochemical properties were being widely discussed during 1988 and 1989, three groups independently published their results in 1990. First, the Joyce group reported the use of in vitro mutation, selection and amplification to isolate RNAs that were able to cleave DNA.\(^3\) They began with a natural RNA-cleaving ribozyme, rather than a purely random library, and were looking for a novel enzymic activity rather than a selective ligand. However, their experiment had most of the essential features described in this article, including the repeated cycles of reaction performed in a single vessel. Second, the Gold group described experiments designed to identify the sequence requirements of T4 DNA polymerase, in which the library was based on the natural target hairpin structure but with the eight loop nucleotides randomized.\(^4\) The process of in vitro selection, for which they coined the term ‘SELEX’ (selective expansion of ligands by exponential enrichment), was able to identify the natural target of the enzyme as the predominant, high-affinity ligand, with one major variant emerging with similar affinity. The authors patented their process. Less than a month later, the Szostak group reported the use of in vitro selection to isolate ‘molecules with specific ligand-binding activities’.\(^5\) More radically than the previous reports, they began with a library that was structurally unrelated to any known nucleic acid, having 100 nucleotides of randomized sequence, and chose targets that had no previously identified nucleic acid ligands. They used affinity chromatography to isolate RNAs with specific and selective binding characteristics for a number of organic dyes (chosen because of their potential as H-bond partners and their planar structures that might be expected to form stacking interactions with the nitrogenous bases of RNA). It was this group that coined the term ‘aptamer’ for such nucleic acid ligands.

2.3 Choice of Chemistry

Aptamers are nucleic acids that can be composed of naturally occurring monomers or chemically synthesized derivatives. For a review of this field, see Eaton and Piekten.\(^6\) As outlined above, the nucleotides must be compatible with RNA-dependent DNA polymerases (reverse transcriptase) and with DNA-dependent RNA polymerases (such as T7 RNA polymerase) for the enzymatic steps required in the production of RNA-based aptamers, or with thermostable DNA-dependent DNA polymerases (such as Taq polymerase) for the production of DNA-based aptamers.\(^7,8\) This restricts the available chemistry more strictly than is the case with purely synthetic oligonucleotides. Nevertheless, researchers have adopted many modifications of natural nucleotides in order to overcome two substantial problems posed by natural nucleic acids.

2.3.1 Phosphodiester Bond Hydrolysis

This is a particular problem in natural RNA, as the hydroxyl at the 2' -position is reactive, particularly at higher than neutral pH, and will attack the neighboring phosphodiester bond to produce a cyclic 2',3'-phosphate, thereby breaking the nucleic acid backbone (see Figure 2). This reaction is catalyzed by many transition metals ions, particularly lead and iron, and by a range of ribonucleases found ubiquitously in biological samples. To overcome this problem, one has turned to modifications of either the 2'-position of the ribose moiety or modifications of the phosphodiester backbone. By far the most common approach is the use of nucleotides substituted at the 2'-position with either an amino group or fluorine atom. These modifications were pioneered

APTAMERS
where they have been compared, 2'-deoxy and 2'-amino chemistries have been found to produce aptamers with similar affinity, although different structure (for an example, against immunoglobulin E (IgE), see Wiegand et al.\(^\text{12}\)). However, 2'-fluoro chemistry produces aptamers with greater thermal stability and probably higher affinity than 2'-deoxy or 2'-amino chemistry.\(^\text{13}\)

Although one cannot generally change the chemistry of the nucleotides after selection without changing the structure of the aptamer and frequently abolishing its properties as a ligand, this can often be done in a more selective manner (A. Tahiri-Alaoui, unpublished work). For example, further modifications at the 2'-position that give additional stability can be incorporated synthetically into aptamers with 2'-OH, -H, -NH\(_2\) or -F that have been identified through in vitro evolution. For example, 2'-O-methyl has been introduced at certain purines in 2'-F-pyrimidine aptamers against the vascular endothelial growth factor (VEGF), with beneficial effects.\(^\text{14}\)

The alternative approach, to modify the phosphodiester backbone, is more challenging to the enzymology of in vitro evolution. Nevertheless, by using \(\alpha\)-thio-substituted deoxynucleoside triphosphates (dNTPs), a phosphorothioate DNA library was successfully screened for aptamers against the transcription factor NF-IL6,\(^\text{15}\) and some progress has been made toward the use of analogous, ‘thio-RNA’ aptamers.\(^\text{16,17}\)

Another way to produce nuclease-resistant aptamers is to select an aptamer that binds the enantiomer of the eventual target, then synthesize the enantiomer of the aptamer as a nuclease-insensitive ligand of the normal target. Such ‘spiegelmers’ have been made in L-DNA against the peptide hormone, vasopressin\(^\text{18}\) and in L-RNA against L-adenosine and L-arginine.\(^\text{19,20}\)

### 2.3.2 Absence of Hydrophobic or Basic Residues

In contrast to proteins, nucleic acids are strikingly uniform in their hydrophilicity and low \(pI\). In spite of these limitations, a surprising range of enzymatic activities are possible for nucleic acids and the hydrogen bond and stacking interactions of their component bases provide a diverse toolbox of structural motifs.\(^\text{6}\)

Nevertheless, this uniformity almost certainly limits the ease with which aptamers can be made to certain targets and a greater range of side chains, including some with basic or hydrophobic character would be welcome additions to the armamentarium. The challenge, as with substitutions giving nuclease resistance, is to discover approaches that are consistent with the enzymes used during aptamer isolation. One approach, using 5-(1-pentynyl)-2'-deoxyuridine, succeeded in producing additional aptamers to thrombin,\(^\text{21}\) though no reports
have emerged showing that this approach has produced aptamers against more refractory targets.

It has long been speculated that the precursor to our DNA-genome, protein-catalyst world of organisms was a world in which RNA functioned for genomes, ligands and enzymes and this was consolidated by the discovery of ribozymes. (In his paper on the ‘Evolution of the Genetic Apparatus’, Orgel speculated on ‘life based on nucleic acids without a genetic code’ and said that ‘it seems to me quite possible that polynucleotide chains could make primitive selection among organic molecules such as amino acids by forming stereospecific complexes stabilized by hydrogen-bonding and hydrophobic interactions’. He also speculated that polynucleotides might have the ability in early stages of life to catalyze chemical reactions but that this ‘function would subsequently have been taken over by the much more versatile polypeptides’.) Indeed, it is proposed by some that the restricted range of amino acids extant in the current world of biology is dictated by those homologous with natural, prebiotic derivatives of 5-hydroxymethyluracil that had previously been a feature of the ‘RNA world’. Further, one should note that many biological RNAs of the present world have additional methyl groups added post-transcriptionally to their purines, which increase the local hydrophobicity of the nucleic acid (reviewed by Levy and Miller). None of these potentially helpful modifications is reproduced during enzymatic replication of nucleic acids, though some of them, rather than acting as chain terminators, are ignored. For example, 5-methylation of cytosine is a common post-replication modification of eukaryotic DNA and 5-methyldeoxycytidine is replicated routinely to dG during the S phase of the eukaryotic cell cycle.

Instead of attempting to broaden the repertoire of nucleotides used during the replication and transcription phases of in vitro selection of aptamers, one might modify one or more nucleotides post-transcriptionally. It was found that derivitization of 2'-NH$_2$ groups on aminopyrimidine-RNA with succinimide did not prevent reverse transcription. Although this might usefully open up a wide range of functional adducts, the efficiency was low, with only two out of 23 amino groups per molecule, on average, being successfully derivatized. In order to preserve the genetic encoding of aptamers, it is essential that such processes are either fully efficient or reproducibly inefficient (i.e. the same nucleotides being derivatized each cycle).

### 2.4 Practical and Theoretical Considerations

A comprehensive and practical introduction to the methodology of in vitro evolution of RNA ligands was provided by Fitzwater and Polisky and so will not be repeated here. A mathematical description of the process, under assumptions of equilibration, was produced by Irvine et al. and supplemented by a model for simultaneous selection against multiple targets by Vant-Hull et al. We shall confine ourselves to a discussion of some of the most relevant details.

#### 2.4.1 Library Complexity

When designing a library, the desire is to produce sequences that can be amplified and transcribed with high efficiency, of as great a diversity of structures as is practicable and at reasonable cost. One is bound to use substantial fixed, flanking regions for primer-based amplification and transcription, so one question is how long to make the randomized region (N) and how to ensure that the library produced contains as near to the theoretical maximum of sequences possible. First, although the sequence space available to the library is 4$^N$, the maximum number of molecules that can be manipulated in standard molecular biology laboratories (M) is of the order of 10$^{13}$, and errors of synthesis and workup have been estimated to reduce this diversity to 10$^{13}$–10$^{14}$. N need only be around 22–24 to reach this practical limit. However, in order to produce a structure capable of specific interaction with a target molecule, the RNA needs to be large enough to fold into a complex tertiary structure. It appears that many classes of RNA fold need to composed of significantly longer stretches of nucleic acid than this (see above), so most people use libraries where N ≥ 35 and sometimes much more. As N increases, one is able to sample progressively a smaller fraction of the theoretical sequence space. For example, if M = 10$^{14}$ and N = 24, we could sample (10$^{14}$/2.81) × 10$^{14}$ = 36% of the sequence space, but if N = 25, this reduces to 8.9%. However, if we consider each 25-mer to be composed of two overlapping 24-mers which differ only at their termini, then the N = 25 library effectively contains 2 × 10$^{14}$ 24-mers. This suggests that one should aim for larger rather than smaller values of N. Two considerations effectively limit the practical size of N. First, although the efficiency of oligonucleotide synthesis is constantly improving, errors accumulate with each cycle and a point is reached at which incorrectly synthesized molecules begin to have a significant impact on the quality of the library. The limit is imprecise but it seems unwise at present to make large-scale libraries using oligo lengths much greater than about 120 nt, suggesting a practical limit of around N = 70–80. Second, if RNA folds are typically between 25 and 50 nt long, libraries with N greater than approximately 50 nt may well contain sequences comprising two independent folds, complicating the process of in vitro selection. The actual diversity of a library can be compromised by variations in the efficiency of coupling phosphoramidite
monomers during oligonucleotide synthesis, which in turn can depend on the particular practices of the manufacturer chosen. Although standard methods use equimolar mixtures at each N stage during synthesis, the Szostak group has reported the use of an A:C:G:T ratio of 3:3:2:2 and we have found it necessary to use ratios of 6:5:5:4 in order to achieve random incorporation. Gross bias during synthesis and enzymic manipulation can be estimated by checking the sequence of a dozen or so clones made from the library after a single round of amplification, transcription, reverse transcription and reamplification, without selective partitioning. The clones should be sequenced and the overall base composition within the random region tested for divergence from expectation. In addition, one should look for bias in the dinucleotide and trinucleotide composition and at base composition at each position.

What are the chances of finding a target-binding sequence during the in vitro exploration of sequence space? The answer seems to depend on one’s target and the criteria (e.g. affinity threshold) used to identify binding. For example, within the N = 100 library described by Ellington and Szostak, the authors estimated that 10% of the library contained aptamers for organic dye molecules. In contrast, Burke and Gold estimated that perhaps one in 10$^{11}$ sequences within their library contained adenosine-binding motifs. Our own experience with libraries of N = 36 is that protein-binding aptamers sequences exist at an initial frequency of typically 1 in 10$^{11}$–10$^{12}$. If these figures are representative, it shows that care needs to be taken during the early stages of library production and manipulation not to reduce the sequence complexity much below its theoretical maximum.

Tuerk has made calculations based on computer modeling of the SELEX process and suggested that binding reactions that yield 6% of the total RNA bound to target would be optimal. Schneider et al. showed that when reactions were arranged to select 10% of the RNA population bound to the target protein (low stringency) or 1% (high stringency) during SELEX, ligands of similar sequences were produced by both selection strategies, although the speed of affinity enhancement of the pool was increased somewhat for the high stringency selection. This illustrates that the fine tuning of ligand–target ratios is not crucial for success in obtaining optimal binding ligands. Tuerk suggests that the first binding reaction be conducted in large volumes (50 mL) with target molecule concentrations at 0.2 times the $K_D$ of the original nucleic acid pool–target interaction and all of the starting nucleic acid. This would yield about 9% of the original nucleic acid population bound to a large number of target molecules, decreasing the chance that low-abundant, unique sequences of high affinity are lost in the first selection.

2.4.2 Mutagenesis and Affinity Maturation

Thus far, we have been considering merely the selection of ligands from an initially very small and approximately random sample of sequence space. However, the phrase ‘in vitro evolution’ implies that we are able to explore a much greater fraction of sequence space by allowing mutation to generate additional diversity and selection to retain a small fraction with favorable properties. By repeatedly selecting for the desired property, the path of exploration should tend towards optimum ligands; those that occupy segments of sequence space that correspond to affinity maxima. However, we can imagine many ways in which this favorable result would not have been reached. First, the initial sample of the library may not have contained any members that were within striking distance of a high-affinity region of sequence space. This will depend on the complexity of the library and the nature of the target, as described above. Second, the amount of mutation at each level may have been too little to allow significant progress towards the affinity maximum. Conversely, mutation might have been so high that the peaks would have been missed or overshot. Third, selection might not have been stringent enough, allowing the minority of high-affinity ligands to be swamped by their low-affinity brethren. Conversely, selection might have been too stringent, eliminating sequences of intermediate affinity before high-affinity sequences had been arrived at. This is a particularly acute problem during in vitro selection because one rarely has any way of knowing either the affinity topology of sequence space or the properties of early-cycle oligonucleotides.

There has been surprisingly little experimental analysis of this problem. Although we know that aptamers selected against a particular target usually fall into sequence groups which suggest phylogenetic relatedness, the polyphyletic origin of aptamers means that two similar sequences may have arisen by convergence from two independent sequences sampled in the initial library as easily as by divergence from a common ancestor. Nevertheless, in one study, explicit evolution was measured from an aptamer that had been previously selected against L-citrulline to others which could bind alternative amino acids. Mutation was introduced at a single step by chemical resynthesis of the original aptamer to give an average of 30% mutation at each position. Binding to citrulline was recovered after three rounds of selection and to arginine after four rounds. However, no lysine- or glutamine-binding aptamers were obtained. The more usual method of introducing mutation is to encourage misincorporation of nucleotides during amplification by increasing the concentration of dNTPs and Mg$^{2+}$ and using enzymes lacking proofreading activity.
2.4.3 Partitioning Methodology

The separation of desired from undesired sequences is of critical importance in the selection and evolution of aptamers (see the discussion above and a mathematical analysis by Vant-Hull et al.\textsuperscript{(30)}) Ideally, one would be able to allow the nucleic acid pool and the target to interact freely, be able to monitor the progress of the interaction and retain those nucleic acids whose desired property lay above a threshold determined in part by the properties of the pool. Most methods of partitioning fall short of these ideals. First, tethering the target to a solid support facilitates the separation of bound from unbound nucleic acids and facilitates procedures such as competitive elution which can be helpful in setting affinity and specificity parameters. The partitioning of target to Sepharose has also been used for this purpose.\textsuperscript{(29)} Second, immobilization reduces the mobility of the protein, impeding its mixing with nucleic acid and may produce direct steric hindrance to aptamer binding. Third, a progressive reduction in the molar ratio of target protein to nucleic acid in successive cycles, in order to increase the stringency of selection, is very hard to achieve in an immobilized system. Consequently, one of the common approaches is to use an insoluble matrix that selectively absorbs protein following nucleic acid–protein interaction in the fluid phase. Nitrocellulose filters are a cheap and convenient matrix that is widely used for this purpose.\textsuperscript{(4,39,40)} However, we have found that nitrocellulose preparations are not as selective for protein as would be desired. We have compared the use of nitrocellulose filters, poly(vinylidene difluoride) (PVDF) membranes, activated Sepharose, octyl Sepharose and the deproteinizing matrix Strataclean\textsuperscript{™} resin for their ability to select for CD4-binding aptamers via interaction with the protein (F. Kesten, personal communication). We found that nitrocellulose and PVDF trapped substantial amounts of 2'-F-RNA nonspecifically and that octyl Sepharose was not an efficient protein binder under these circumstances (results not shown). However, CNBr-activated Sepharose and Strataclean\textsuperscript{™} resin were both efficient at pulling down 2'-F aptamer RNA in a target-dependent fashion (see Figure 3).

Models of the selection process also assume that equilibrium between RNA and protein has been reached before partitioning.\textsuperscript{(29)} However, this is very unlikely to be the case during early rounds, when the concentration of ligands is extremely small or at any stage when incubation times of the order of 10 min are used routinely and the most desirable aptamers have dissociation $t_{1/2}$ of the order of 1 h (J. Ibrahim and L. Frigotto, personal communication). In a recent study, we were able to show that increasing the incubation time from 30 min to 2.5 h substantially reduced the number of cycles required to isolate high-affinity aptamers.\textsuperscript{(41)} Recent improvements in robotics technology have enabled the process of in vitro selection to be reduced to a matter of days.\textsuperscript{(42)}

2.4.4 Structural Pleiomorphism

A central but unspoken assumption of the methods for in vitro selection and evolution of aptamers is that there is a direct and unique relationship between the sequence of an aptamer and its shape: the ‘one sequence, one structure’ assumption. In other words, if one selects a nucleic acid sequence $s$ in round $n$ on the basis that it binds to protein X, then one would expect that all copies of the amplified sequence $s$ will bind to X in round $n + 1$. However, if sequence $s$ can fold into more than one conformation, only a proportion of the reamplified $s$ will bind to X in round $n + 1$. Worse, if each sequence is present at low copy number, for example during the early rounds of selection, the copy of sequence $s$ in round $n$ may not be in the right conformation to bind X and thus not be selected at all. How pleomorphic should we expect most RNAs to be? If we were to answer this on the basis of the known folding of functional RNAs such as the Tetrahymena intron or the hammerhead ribozyme, which fold rapidly into their native states, we might be misled. Instead, if we look at most monoclonal aptamers, it is not uncommon to discover that they comprise distinct conformers, only a minority of which are competent ligands (A. Tahiri-Alaoui and E. Kraus, personal communication). During selection, one would expect the selective process to favor those RNAs that are minimally pleomorphic, so the persistence of this property in aptamers suggests that...
pleiomorphism is common in unselected oligonucleotides. RNA folding algorithms, admittedly still only able to predict approximately 75% of experimentally determined base pairings, indicate that a given sequence is frequently capable of folding into several structures, each with similar ΔG. If the free energy barriers between any of these folded forms are great enough, multiple conformers would be expected. Natural evolution of, for example, ribozymes, would have imposed a selective pressure for sequences whose folding pathways are more uniform or for an association with chaperone-like proteins that would favor one conformation over another. Those working with aptamers have adopted a variety of strategies to minimize this problem – from snap-cooling nucleic acid pools from the denatured state to a slow refolding procedure – but none is entirely successful. Although technically challenging, it is becoming possible to analyse co-existing structures within a population of RNA molecules with identical sequence.

Conformational flexibility has been observed in protein–aptamer interactions, for example, an induced fit in the target polypeptide following the binding of aptamers raised against the HIV-1 regulatory protein. Conversely, the conformation of the nucleic acid was seen to change upon binding of an RNA aptamer to its amino acid target.

3 PROPERTIES OF PUBLISHED APTAMERS

3.1 Structures
The structure of a large number of aptamers has been determined by enzymatic or chemical probing, nuclear magnetic resonance (NMR) and X-ray crystallography (see reviews by Feigon et al. and Patel). They are relatively amenable to NMR methodology because of their small size and their rigidity when complexed with target. Although the fundamental repertoire of nucleic acid secondary structures is radically different from that of proteins, the similarities between the interaction sites between protein ligands and their receptors can be strikingly similar to those of aptamers. A few of the salient features are described below.

3.1.1 DNA Aptamers
One of the earliest aptamers studied structurally was the 15mer DNA aptamer against thrombin, d(GGTTGGTG-TGGTTGG), isolated by Bock. Using two-dimensional proton NMR, it was shown that this short oligo folded tightly into a four-stranded structure, stabilized by two stacked G tetramers, with each of the two pairs of strands having a TT dinucleotide loop (see Figure 4). X-ray crystallography of the aptamer complexed with its target showed that the aptamer was sandwiched between the two highly basic exosites of thrombin, making no contact with the active site at the base of the cleft between the two exosites. The X-ray and NMR models were very similar, but the polarity of the strands was different, with the two TT loops spanning the major groove in the X-ray model and the minor groove in the NMR model. These two structures are technically very hard to discriminate from the crystallographic data, and it is probable that the NMR model is, in fact, correct. Another GT-rich oligo, d(G'TGGTGGGTGGGG'T) (where the first and last phosphodiester bonds are replaced with phosphorothioate), was found to be an inhibitor of the integrase enzyme of HIV-1. The structure of this aptamer is again four strands, stabilized by a pair of G quartets but in which the joining loops are all TG. The G octet is not the only kind of structure adopted by DNA aptamers, however. For example, an aptamer against argininamide is a hairpin loop, which undergoes a rearrangement upon binding to its target, in which the loop is reflexed to trap the amino acid between the stem and the stabilized loop by a combination of H-bonds and stacking interactions.

3.1.2 RNA Aptamers
Aptamers based on RNA, or nucleotides with predominantly RNA-like properties, are capable of adopting a seemingly greater variety of structures (reviewed by Patel and Ferre-D’Amare and Doudna). For example, a flavin mononucleotide (FMN)-binding aptamer consists of an asymmetric loop that binds the target, flanked by two A-form helices. The asymmetric loop itself forms a widened, colinear helix comprising an anti purine pair and a base triple at one side, two anti purine pairs at the other of the intercalated isoalloxasine moiety of FMN (see Figure 5). Essentially, the target is acting as a highly abnormal intercalated base in a modified double helix. Another nucleotide-binding aptamer, which recognizes adenosine 5’-monophosphate (AMP), incorporates its target even more intimately into its structure. Tetraloops of consensus sequence GNRA (where N is any nucleotide and R is a purine) are
common in natural RNAs and are particularly stable. The AMP-binding aptamer was found to recruit the free AMP and thereby form a GNRA-like loop from a region that is unpaired in the absence of a target. The structures of protein-binding aptamers show further variations on these themes. For example, aptamers that bind the HIV-1 regulatory protein, Rev, accommodate an α-helix of their target within a modified major groove that is widened by the presence of a number of non-Watson–Crick base pairs. In contrast, a class of aptamers that bind the reverse transcriptase of HIV-1 possess a compact form of pseudoknot structure (see Figure 6) which is believed to occupy the groove within the enzyme normally occupied by its kinked template. A biotin-binding aptamer was also found to have a rigid pseudoknot structure. The pseudoknot represents just one class of structural element or fold exhibited by functional RNAs. The common feature of these folds is that they allow the molecule to be more compact than the classical A-form double helix (reviewed by Ferre-D’Amare and Doudna) and thereby take on a more globular form, which is perhaps more suited to ligand recognition.

### 3.2 Aptamer Size

It has already been noted that the sequence space available to most libraries used in aptamer isolation exceeds the practicable limit of molecules that can be handled. Moreover, for many applications it is desirable that the aptamer should be as small as possible, on costs grounds, reasons of target accessibility and so on. Nevertheless, because functional RNA folds have a finite size, the minimum length of aptamers is often larger than the size that generates a manageable sequence space. Further, the size of aptamer that is initially recovered from a process of in vitro selection is inflated by the flanking, fixed sequence regions, required for amplification and transcription, which may add up to 50 nt. A combination of deletion analysis, footprinting and in vitro synthesis can be used to determine the shortest stretch of nucleic acid that can bind to the target. The size range of minimal aptamers is fairly wide and the following give some indication. The minimum motif within VEGF aptamers was between 23 and 35 nt (depending on sequence family); minimum xanthine- and guanine-binding aptamers were 32 nt long; streptomycin-binding aptamers were 46 nt long; and the minimum region of an aptamer that binds a serine protease of the blood (protein C) may be as much as 99 nt long. This gives an $M_r$ range of 7.5–32 kDa for aptamers, with 10 kDa being typical. The solvent-exposed surface area for a typical aptamer would be expected to be in the range 50–60 nm$^2$

### 3.3 Aptamer Targets

Can aptamers be raised against any target molecule? Put another way, can the lack of chemical diversity among nucleic acids be compensated by the size of the sequence space that can be sampled and the resultant structural diversity of aptamers? The evidence is that aptamers can be generated against small ions, such as Zn$^{2+}$ to nucleotides such as adenosine triphosphate (ATP), oligopeptides and large glycoproteins such as CD4 spanning the size range 65 Da–150 kDa, with no theoretical upper limit. The chemical classes of targets are reasonably diverse, including organic dyes, neutral disaccharides, amino-glycoside antibiotics (see Figure 7), dopamine, a porphyrin and biotin.

Nevertheless, there is evidence for a strong degree of bias, among protein-binding aptamers, for a limited number of sites. First, a surprisingly high proportion of proteins against which aptamers have been described are themselves ligands for polyanions such as nucleic acids or glycosaminoglycans. These include thrombin and other proteases of the clotting cascade, a number of heparin-binding growth factors and viral regulatory factors and viral regulatory
NUCLEIC ACIDS STRUCTURE AND MAPPING

10

Figure 7 NMR-derived structure of a tobramycin-binding aptamer, bound to its target. (Data derived from conformer 1 of 13 published by L. Jiang and D.J. Patel, ‘Solution Structure of the Tobramycin – RNA Aptamer Complex’, *Nature Struct. Biol.*, 5(9), 769–774 (1998).) (a) The phosphodiester backbone of the aptamer is depicted as an orange cylinder and the tobramycin is shown in ball-and-stick form. (b) The aptamer is shown as a wireframe model with the base identities and positions labeled.

proteins. It has even been reported that some heparin-binding proteins, such as thrombin, may have natural plasma aptamers.

Second, when the aptamer-binding sites (or aptatopes) on large target proteins are mapped, it is usually found that they are coincident, even if the aptamers fall into unrelated sequence families. For example, all six of the distinct classes of aptamer against VEGF were found to bind to the same region, competing with heparin and other natural ligands and being cross-linkable to the same cysteine and four structurally distinct aptamers against reverse transcriptase all bound the same region of the enzyme. More strikingly, when five different sequence classes of aptamer against CD4 were analysed, all bound to a single region of one of the four immunoglobulin (Ig)-like domains, in contrast to monoclonal antibodies, which define several epitopes in each domain.

This focusing of aptamer reactions on a small fraction of a large macromolecular target suggests that the process of in vitro selection does not proceed entirely according to simple models of multitarget partitioning. Rather, it suggests that favorable and unfavorable aptatopes are distinguished by differences of affinity of many orders of magnitude. It seems likely that a major obstacle is that the Coulombic repulsion between the phosphate-containing backbone of nucleic acids and negatively charged amino acid and sugar residues at the surface of many proteins and glycoproteins produces extremely low association rates. This would mean that only a small proportion of the surface of the macromolecule would be ‘visible’ to aptamers, probably regions of high solvent exposure in which positively charged residues provided a degree of electrostatic steerage towards the aptatope. This has been most closely studied in the case of antithrombin DNA aptamers. By mutating a critical arginine to glutamate, the binding of aptamers was abolished. The mutant form of thrombin was then used to raise further aptamers and these were found still to bind regions homologous to that recognized by the first-generation aptamers.

3.4 Affinity

The affinity of published aptamers varies very widely. Generally, aptamers against small molecules have affinities in the micromolar range. For example, aptamers against amino acids such as citrulline and arginine range from 0.3 to 65 µM, those against ATP and xanthine were 6 and 3.3 µM, respectively, and those against dopamine were 2.8 µM and those against vitamin B12 were 90 nM. Aptamers to nucleic acid-binding molecules typically have affinities in the nanomolar range. For example, aptamers against retroviral integrase, reverse transcriptase and nucleocapsid proteins were 10–800, 0.3–20 and 2 nM, respectively, and approximately 0.8 nM against the ribosomal RNA (rRNA)-binding aminoglycoside antibiotics. Affinities in the nanomolar to subnanomolar range are found against heparin-binding proteins. Examples include platelet-derived growth factor (PDGF) (0.1 nM), basic fibroblast growth factor (low nanomolar), thrombin (25 nM), VEGF (approximately 100 pM), keratinocyte growth factor (approximately 1 pM) and
the heparin-binding non-pancreatic, secretory phospholipase A2 (1.7 nM). Aaptamers against proteins that do not bind heparin or nucleic acids have typically lower affinities. For example, those against the oncoproteins K-Ras and Raf-1 were 0.14–1 µM and 300 nM, respectively. One to substance P had a KD of 190 nM, and one to the NS3 protein of hepatitis C virus had a KD of 650 nM. Immunoglobulin class G (IgG) superfamily domain-containing proteins seem to be able to elicit aptamers in the 2–40 nM range of affinity and this might relate to their ability to interact with other cell-surface glycoproteins.

4.1 Conjugation to Detectable Moieties

Often, the first step in exploiting an antibody is its conjugation to a detectable moiety, such as a fluorochrome, an enzyme or a generic ligand such as biotin. Conjugation is most usually done by derivatizing ε-amino groups of lysines on the antibody molecule, but care has to be taken not to block lysine residues near or within the complementarity-determining regions. Conjugation can be done through carbohydrate side chains, but this is much less usual. Even more commonly, secondary antibodies, which recognize conserved epitopes on antibodies, irrespective of their antigen, are conjugated to detectable moieties, thereby simplifying the development of assays for new antigens. The challenge of aptamers is to develop a generic labeling system that does not tend to disrupt aptamer structure or hinder interaction with target. Nucleic acids can be radioactively ‘body labeled’ during transcription or replication by the use of modified nucleotides. Where these are 3H or 32P body labeled, this does not affect the chemistry of the aptamer and thus does not affect its properties as a ligand. This is a very common way of quantitating the binding of an aptamer or a pool of nucleic acids to the target molecule. In addition to body labeling, site-specific labeling with a radionuclide can be useful, for example where the aptamer is synthesized chemically. For example, in one case, a stannyl nucleotide was incorporated at the 5’ end of a DNA aptamer during chemical synthesis and tin was subsequently replaced by 123I in an oxidation reaction. The aim was to produce a ligand that can be used for in vivo imaging.

Aptamers can also be labeled using fluorochromes or reactive groups. Here, the challenge is to introduce the detectable groups at positions that do not interfere with ligand properties. For example, a chemically synthesized aptamer against human neutrophil elastase was labeled at either the 3’ or 5’ end with fluorescein or biotin. It was found that incorporation of the label reduced the affinity of the aptamer unless a substantial spacer was used. In vitro transcribed aptamers can have biotin or fluorochromes incorporates as body labels but this is generally at the expense of their properties as ligands. Labeling at the 3’ end can be achieved in a number of ways:

3.5 Specificity

When measured, it has been found that those targets that give rise to very high-affinity aptamers have measurable affinity for unselected RNA. For example, the E. coli β protein has an affinity for unselected RNA in the 1 µM range and can be used to isolate specific aptamers that bind with an affinity of approximately 1 nM. This observation suggests that the assertion that high affinity necessarily produces high specificity is unsafe, but the evidence suggests that aptamers can show a great deal of specificity. First, different enzymes with similar specificity necessarily produce high specificity. Second, different enzymes with similar specificity are able to elicit aptamers in the 2–40 nM range of affinity.
by templated extension using Klenow polymerase,\(^\text{112}\) by T4 RNA ligase-mediated ligation\(^\text{113}\) and by terminal deoxynucleotidyl transferase.\(^\text{114}\) Labeling at the 5’ end can be achieved by the supplementation of the in vitro transcription mix with an excess of GTP-β-S, the thiol of which can then be used to attach biotin (see Figure 8).\(^\text{115}\) This approach was used successfully to multimerize an anti-CD4 aptamer via streptavidin, which in turn allowed a fluorochrome to be attached to the aptamer for use in flow cytometry.\(^\text{115}\) We have already discussed the problems associated with inefficient derivitization of internal 2’-amino groups.\(^\text{27}\)

4.2 Apatmers in Biosensors and Other Detectors

As high-affinity, high-selectivity ligands, aptamers have potential in a range of detection systems, including biosensors (for reviews, see Osborne et al.\(^\text{116}\) and Bier and Furste\(^\text{117}\)). We have already discussed their application in flow cytometry\(^\text{115,138}\) and they can also be used in sandwich assays akin to enzyme-linked immunosorbent assay (ELISA).\(^\text{119}\) Fluorescently labeled aptamers have also been used to quantitate IgE and thrombin using a rapid method based on capillary electrophoresis/laser-induced fluorescence (CE/LIF), in which detection down to 50 pM was reported.\(^\text{120}\)

Unlabeled aptamers can also be used in certain analytical methods. For example, surface plasmon resonance (SPR) methods, such as those exploited by the BIAcore system, have been used to detect activated 2’,5’-oligoadenylate synthetase and CD4.\(^\text{38,121}\) In these cases, the aptamer was in the mobile phase and the target was immobilized. However, with appropriate derivitization and immobilization, aptamers could be used to detect specific molecules in complex mixtures using SPR.

Perhaps the most exciting method so far described also depends on an optical flow cell system and the evanescent wave from a total internal reflection event at the optical surface. However, in the application described by Potyrailo et al.\(^\text{122}\) the effect detected is not on plasmon resonance angle but on fluorescence anisotropy. They reported that fluorescent aptamers immobilized at the optical surface could be used to detect as little as 0.7 amol of thrombin in a 140-pL test volume in just a few minutes.

Other methods that might be applicable to aptamer-based detection in the future include thin-layer interference techniques which have been used to measure DNA – small molecule interactions in real time.\(^\text{123}\)

4.3 Apatmer Combination

One approach to increasing the usefulness of aptamers is to combine them with another ligand. For example, a DNA aptamer to human neutrophil elastase was noninhibitory to the enzyme’s protease activity but improved the \(K_i\) of a weak peptide inhibitor by five orders
of magnitude when the two were conjugated through an N-methoxysuccinyl link.\(^\text{124}\) Alternatively, one can link aptamers together to form a dimeric or multimeric ligand. This can take the form of joining identical aptamers, perhaps to increase affinity by reducing the dissociation rate of the complex from a multimeric target, or of joining aptamers against different aptatopes, in order to change specificity. An example of the former approach was the homodimerization of aptamers against L-selectin, which resulted in ligands with \(K_D\) in the range of good monoclonal antibodies.\(^\text{118}\) The procedure is not straightforward, however, as linking two aptamers in a single oligonucleotide can result in loss of function for one or both ligand moieties, either by steric hindrance or by disruption of the folding of each module. This problem was found with combinations of aptamers against coenzyme A, chloramphenicol and adenosine, but was overcome by the use of further rounds of in vitro selection on chimeric RNAs in which the junctions between aptamers were diversified.\(^\text{125}\) A practical use for heterodimerization of aptamers has been the linking of aptamers that recognize thermostable polymerases but with different specificity.\(^\text{126}\) The resultant chimeras had a broad specificity to enzymes from a range of thermophilic species and were potentially useful for improving the efficiency of PCR from low-copy-number templates. A further potential application of heterodimerization is to link an aptamer that recognizes a target molecule of analytical interest to a second aptamer that recognizes a detectable molecule, such as a fluorochrome.\(^\text{127}\)

Aptamer modules have also been linked to ribozymes (catalytic RNAs) to provide a means for controlling enzyme activity through allosteric interactions. For example, the activity of a hammerhead autocatalytic ribozyme fused to an ATP-binding aptamer was shown to be regulated >100-fold by the presence of ATP.\(^\text{128} - \text{130}\) This effect depends on the conformational change in the aptamer following ligand binding and steric hindrance between the folded aptamer and the ribozyme. These and other authors have extended this work to construct RNA-cleaving ribozymes whose activity is regulated by other small molecules, such as theophylline and FMN,\(^\text{129}, \text{131}\) and RNA-ligating ribozymes whose activity is regulated by ATP.\(^\text{132}\) The general principle could form the basis of a new generation of in vitro assays for analytes.

### 4.4 Use of Aptamers In Vivo

Since the lead given to the field at the turn of the century by Paul Ehrlich (see, for example, Ehrlich\(^\text{133}\)) (translation by Brock\(^\text{134}\)), there has been a continuing desire to develop new classes of specific ligands, preferably by rational means, that could act as 'magic bullets', seeking out their molecular targets in vivo and destroying them. The possibility that aptamers might be candidate therapeutic agents has naturally received much attention (see review by Osborne et al.\(^\text{119}\)). The main challenge to all these applications is the pharmacokinetics of oligonucleotides in vivo: the rate at which they are degraded by plasma nucleases; the rate at which they are sequestered by reticulo-endothelial cells and plasma proteins; the rate with which they are excreted by the kidney; and the rate at which they redistribute from the blood to the tissue or body fluid of interest. Natural, 2'-OH-RNA degrades very rapidly in human serum in vitro but this process can be slowed at least 1000-fold by 2'-amino modification.\(^\text{135}\) In vivo studies on the \(f_{1/2}\) of single-stranded DNA aptamers gave values in the range from <2 min to approximately 8 min.\(^\text{136} - \text{138}\) Conjugation of the aptamer to either lipids or polyethylene glycol has been reported to improve the stability and distribution kinetics of DNA aptamers sufficiently to produce therapeutic effects.\(^\text{139}, \text{140}\) A wide range of potentially therapeutic targets for aptamers are summarized in Table 1, with a note of therapeutic effect or clinical benefit, if any.

More radically, it is conceivable that one could use aptamers in a form of gene therapy, to inhibit the function of intracellular proteins – either host-derived or viral – in vivo. This approach is fraught by all the problems that have dogged the gene therapy field for many years: inefficient and intrusive delivery systems, inefficient or transient expression, safety concerns, poor selectivity, and so on (for a review, see Palu et al.\(^\text{141}\)). Worse, the rather low concentration of free divalent cations and the presence of high concentrations of RNA-binding proteins in the cell means that aptamers selected under the conventional in vitro conditions might well be inappropriately folded in the cell. Nevertheless, some positive reports have appeared. For example, in a study of the inducible expression of aptamers against RNA polymerase II in yeast, a significant effect on transcription was seen as a result of aptamer expression, but only in yeast strains with abnormally low levels of polymerase II expression.\(^\text{142}\) More promisingly, U6 snRNA and tRNA\(_{\text{met}}\) cassettes were used to express aptamers that bound the HIV-1 regulatory protein, Rev, in cells\(^\text{143}\) and it was found that these, like Rev decoys derived from the natural Rev RNA ligand, were able to inhibit the expression of the virus. However, these experiments were done in vitro in a convenient but unphysiological cotransfection system, so one must be careful not to overextrapolate.

### 4.5 Studies on Nucleic Acid Structure

One of the first studies describing in vitro selection of nucleic acid ligands was designed to analyze the sequence requirements of a nucleic acid-binding

<sup>a</sup> NGF, nerve growth factor; PrP, prion protein.
protein. Apatamers have continued to be a powerful method for analyzing nucleic acid sequence binding requirement of a range of viral proteins. For example, aptamers have been used to dissect the nucleic acid binding sites of the coat proteins of bacteriophages R17, MS2, and φ29, the RNA-dependent RNA polymerase of bacteriophage Qβ, the Epstein–Barr virus EBER1 RNA, the regulatory, Rev-response element of HIV-1, and the HIV-1 nucleocapsid protein.

The approach has been used productively to examine the interaction between components of the translational machinery and natural RNAs, e.g. the elongation factors EF-Tu, eIF-4B, and SelB, the S8 and S1 ribosomal proteins from E. coli, the L32 ribosomal protein of yeast, and the decoding end of 16S rRNA. Finally, transcription and post-transcriptional processing have been amenable to the aptamer approach, e.g. the requirements for the E. coli transcriptional terminator ρ, the eukaryotic splicing factors SF2 and SC35, and GU-rich sequences for efficient polyadenylation. It has been proposed that these methods could be used to identify all the protein–RNA interactions encoded in the genome, although this is not yet an established approach.

### 4.6 Isolation of New Catalysts

The very first paper describing directed in vitro evolution of nucleic acids described the isolation of a totally new enzyme, a nuclease composed of DNA. The possibility was thereby opened up that one could develop any form of useful new catalyst that could be conceived and for which a selection procedure could be devised. To an extent, this has been realized, with the isolation of enzymes that can ligate DNA in a Zn/Cu-dependent fashion or ligate RNA with a similar mechanism to that of protein enzymes. These new enzymes are not restricted to phosphodiester bond formation and breakage. For example, in vitro-selected nucleic acid enzymes have been described that cleave amide bonds and alkylate halogenated peptides. The combination of a fluorochrome aptamer and its target was found to have low-level oxidative activity, when coupled to its target and a hemin–aptamer complex was found to have levels of peroxidase activity comparable with protein peroxidases, and much higher than those of catalytic antibodies. More significantly, RNA enzymes have been selected with amide bond-forming activity in which a uridine was replaced by a 5'-imidazole derivative of uridine, capturing the chemical characteristics of histidine in nucleic acid. Also, a ribozyme was isolated that catalyzed a Diels–Alder cycloaddition reaction in which uridine is replaced by a 5-pyridyl derivative of uridine. This RNA catalyst is therefore the first nucleic acid with carbon–carbon bond-forming activity.

### 5 Perspectives and Future Developments

Clearly, the first decade of research using aptamers has opened up some very exciting avenues in basic and applied research. The power of the technique has surprised many and, even though the chemistry of nucleic acids is much less diverse than that of polypeptides and there are substantial restrictions to the technology as it stands, it is already a useful tool and promises to become more so. There are substantial advances in methods which use the principle of in vitro selection but apply it to the evolution of peptide ligands. For example, adaptations of the two-hybrid display methodology using randomized peptides displayed on thioredoxin in E. coli have been used to generate peptide aptamers against CDK-2 with nanomolar affinity which blocks G1-S transition during the cell cycle of eukaryotic cells engineered to express it. Similar approaches display peptides within the green fluorescent protein or at the C-terminus of the lac repressor protein. One problem with these methods, and the widely used phage display technology [see reviews by Burton and Winter et al.] is that the critical step of passing through a living organism during the generation of the library reduces the number of different molecules that can be screened by many orders of magnitude. To overcome this, methods have been developed to link a nucleic acid-based library with in vitro translation, thereby obviating the need for a living cell. The challenge is to preserve the ‘genetic encoding’ by maintaining the association between nucleic acid and the encoded polypeptide. One approach is to use polysomes, collections of ribosomes simultaneously translating a messenger RNA (mRNA). More conveniently, a method in which translation is simultaneously arrested and the RNA linked covalently to the nascent polypeptide chain has been developed, in which a puromycin group is incorporated at the 3’ end of the library RNA and is linked to the C-terminus of the polypeptide by the action of the ribosome’s peptidyl transferase.

### Acknowledgments

I am grateful for stimulating discussions with Elmar Kraus, Jamal Ibrahim, Laura Frigotto and Abdessamad Tahiri-Alaoui and the opportunity to present their as yet
unpublished results. I thank Abdessamad for his critical reading of the manuscript.

Osaka Prefecture University, Osaka, Japan

1 INTRODUCTION

CE is a powerful and relatively new technique with strong resolution and selectivity for the quantification and qualification of nucleoside bases, nucleosides, nucleotides and nucleic acids, DNA and RNA. Several studies are being carried out to sequence more than 3 billion bases of human DNA by the year 2005, for which cost-effective, high-throughput, and high-fidelity automated sequencing systems are required. CE is an important technique for the analysis of nucleic acids along with conventional electrophoresis and HPLC. CE is becoming popular in nucleic acid analysis because of its extremely high resolution, rapid analysis, ease of automation, and capability of sequence analysis.

There are different CE techniques, which are described elsewhere in this encyclopedia, and they are classified mainly into two groups, that is CE using free solution and electrochromatography. In this article, several types of CE using free solution for nucleic acids are highlighted. These CE methods are based on the electrophoretic separation mechanisms such as CZE, capillary isotachophoresis (CITP), MEKC, CGE, and CAGE. Since these different types of CE provide different information on nucleic acids and their components, the separation mode should be properly chosen to obtain the best performance. The separation mode should be selected on the basis of what information is required about the nucleic acids and what information can be obtained by the selected CE method.

Analysis of relatively small molecules, that is bases, nucleosides, and nucleotide monomers and sometimes even relatively short oligonucleotides, which have...
allows the sequencing of more than 1000 bases within 1 h. Detection with the four- or two-color labeling methods combining the advantages of CGE and laser fluorescence, which has been extensively investigated in the 1990s. Moreover, using CGE, sizing and sequencing of DNA are possible in a shorter time than SGE, since high electric fields can be applied.

The history of CE is briefly described from the viewpoint of the separation mode. A few early studies on isotachophoresis using a narrow-bore capillary were carried out to separate nucleotide monomers.\(^2,3\) CZE using an open-tubular glass capillary was first carried out successfully in 1981 by Jorgenson et al.\(^4,5\) This method is the physicochemical basis of applications of CE to nucleic acid analysis. The earliest successful application of CZE to nucleotides was in 1983.\(^6\) In addition, a successful study for the analysis of short oligonucleotides using MEKC was accomplished in 1987.\(^7\) There have been more than 50 papers published on the analysis of bases, nucleosides, and nucleotides using CZE and MEKC up to 1998, and the practical applications have been extensively investigated. For CZE and MEKC, several types of modification of electrophoretic eluents and additives have been investigated to achieve the best resolution of nucleic acids.

The first successful study of CGE was demonstrated by Cohen et al.\(^8\) in 1988, in which 20 sequences were separated within 20 min using a cross-linked PAG-filled capillary column. In early studies, cross-linked PAG, which was popular for SGE, was used for CGE.

**Figure 1** A guide to select the CE mode suitable for several sizes of nucleic acids. CZE, MEKC, CGE and CAGE cover characterization, size determination, and sequencing of nucleic acids of different sizes.

- **CZE**: Used for larger nucleic acids, double-stranded DNA (dsDNA), and short oligonucleotides.
- **MEKC**: Suitable for nucleotides and nucleosides.
- **CGE**: Suitable for bases and nucleosides.
- **CAGE**: Suitable for monomers.

In addition, CAE in which multiple CE separations are performed in parallel using a number of capillaries and scanned by a laser fluorescence detector is becoming a powerful automatic mapping technique of DNA.
in a fused-silica capillary of which the inner wall was coated. However, the gel-filling technique is often problematic in that bubbles form in the capillary tubing and cause unstable currents. To solve the problems, CGE using noncross-linked PAGs or entangled polymer solutions such as cellulose derivatives as molecular sieving materials have been developed instead of covalently bonded cross-linked PAGs. CAGE is becoming a popular technique for genome mapping since the capillary is replaceable and yields sufficient resolution as high as conventional CGE.

In addition, detection methods have been extensively investigated. Since nucleotide bases have a UV absorption band at 250–270 nm, UV absorption detection is useful for the quantification of nucleic acids, but the sensitivity of UV detection is not high. Laser-excited fluorescence detection was developed and is as sensitive as radioisotopic detection. Further, enhancement of fluorescence detection of DNA by intercalating dye was also developed for the analysis of double-stranded DNA (dsDNA), in which the fluorescence enhancer increases the sensitivity of DNA by a factor of over 1000. The sequence analysis of single-stranded DNA (ssDNA) using fluorescent dye labeling had been extensively developed on the basis of the sequencing technique for SGE. Although CGE separations are rapid, the throughput is about the same as that of conventional sequencing by SGE if only one capillary can be run and detected at a time. The development of a high-speed and high-throughput DNA-sequencing technique was required for the success of the HGP and for this reason CAE was developed in 1992–1993.

Most recently, there has been growing interest in the use of microfabricated devices filled with sieving media for electrophoretic separation of DNA.

### 3 INSTRUMENTATION OF CAPILLARY ELECTROPHORESIS

#### 3.1 Hardware

##### 3.1.1 System

The hardware for CE is described elsewhere in this encyclopedia. A high-voltage power supply, sample injector, and detector are the essential components to run CE. In general, a conventional CE system is sufficient to run CZE, MEKC, and CGE. Normally, commercially available instruments cost approximately US$ 50000–100000. For DNA sequence analysis, a capillary array DNA sequencer is also commercially available.

#### 3.1.2 Detector

Nucleic acids have UV absorption in the wavelength range 250–270 nm, which is due to absorption of nucleoside bases, so that quantification of bases, nucleosides, nucleotides, and size determination of nucleic acids can be performed using a UV detector. For sequence analysis by CGE, a laser-excited fluorescence labeling detection system is required.

##### 3.1.3 Injection

Sample injection can be carried out by several methods. For CZE, MEKC, and sometimes for CAGE, samples are injected by siphoning, electroinjection, injection under vacuum or compression, etc. The electroinjection method involves a short period (a few seconds) of running the electrophoresis. This method is convenient and is sometimes the only possible method in cases where no other injection technique can be applied, such as for CGE. Mechanical injections under vacuum and/or compression injection methods are not suitable for CGE, since gel material is covalently bonded to fused-silica surfaces and these injection methods could destroy the gels in the capillary. Additionally, there is a problem with the electroinjection method in that it is not possible to know whether analytes are homogeneously introduced or not.

##### 3.1.4 Temperature Control

Temperature control is important to obtain the best reproducible data. The influence of temperature for nucleic acid analysis by CGE has been studied.

##### 3.1.5 Capillary

The bore size of the capillary used is frequently 25–100 µm inner diameter (ID) for CZE and MEKC and the coating of the inside of the capillary is not necessary for CZE, but is important for CGE. For CGE, a slightly wider bore capillary (50–100 µm ID) is advantageous to fill molecular sieving materials. The gel-filling techniques are described in a later section. Gel-filled capillaries are commercially available, although somewhat costly.

#### 3.2 Sample Preparation

A general description of sample preparation for CE can be found elsewhere in this encyclopedia. The best performance of CE separation is achieved when analytes are resolved in the same buffer solution used as the running buffer. The concentration should be adjusted to $10^{-5}$–$10^{-3}$ M monomer units of nucleic acids (which corresponds to c. $10^{-3}$–0.1 absorbance scale). For sequencing of DNA using CGA and CAGE with a laser-excited...
fluorescence detector, the detection sensitivity is about \(10^{-12}\) M.

4 SEPARATION AND DETECTION METHODS

4.1 Separation Mode and Theory of Nucleic Acids Migration

4.1.1 Capillary Zone Electrophoresis

Nucleoside bases, nucleosides, and monomeric nucleotides, which are the components of nucleic acids, can be separated by CZE in free solution and MEKC.\(^{28-30}\) In early studies of electrophoresis in narrow-bore capillaries, there had been a few investigations on analysis of nucleotide monomers by CITP,\(^{2,3}\) and a small number of applications as a preconcentration method for CGE have been reported lately.\(^{31,32}\) These methods are not as popular at present as CZE and MEKC.

In CZE, bases, nucleosides, nucleotide monomers and large nucleotides behave differently depending on the \(m/z\). Basically, both electrophoretic flow (EPF) and EOF determine the mobility of analytes in CE. EOF towards the anode occurs if the inner surface of the capillary is negatively charged since an electrical double layer forms on the negatively charged fused-silica surface, which is a regular occurrence when fused-silica capillary tubing is used at neutral pH (Figure 2a). Here, the velocity \(V_{os}\) of EOF is expressed by Equation (1),\(^{33}\)

\[
V_{os} = -\frac{\varepsilon\xi_1}{\eta} E = \frac{l}{t_n}
\]

where \(\varepsilon\) is the dielectric constant, \(\xi_1\) is the zeta potential on the capillary wall, \(\eta\) is the viscosity of the liquid medium, \(E\) is the electric field strength, \(l\) is the effective length of capillary, and \(t_n\) is the migration time of a neutral species. Equation (1) indicates that \(V_{os}\) is positive since \(\xi_1\) is negative for fused-silica capillary tubing at neutral pH. The EOF in fused-silica capillaries is fairly fast at neutral pH and dependent on the surface charge of the inner wall of the capillary (see general description on CE).\(^{34}\)

Analytes migrate at their own electrophoretic speed, which is determined by the \(m/z\). For example, the \(m/z\)

![Figure 2](image-url)
CAPILLARY ELECTROPHORESIS OF NUCLEIC ACIDS

5

decreases in the order of 5’-ATP (adenosine triphosphate) > 5’-ADP (adenosine diphosphate) > 5’-AMP (adenosine monophosphate). The velocity of EPF is expressed in Equation (2),

\[ V_{ep} = \frac{k_0 e \zeta_2}{\eta} f(\kappa a)E \]  

(2)

where \( k_0 \) is a constant, \( \zeta_2 \) is the zeta potential of the solute, and \( f(\kappa a) \) is the function depending on the particle shape. Thus, the mobility of the solutes is controlled by the sum of the electroosmotic and electrophoretic velocities. The apparent mobility of solutes (\( V_s \)) is expressed by Equation (3).

\[ V_s = V_{ep} + V_{os} \]  

(3)

Equation (4) indicates that \( V_s \) is proportional to \( E \) so that faster analysis is possible at higher electric fields. The analytical window between the solvent front and the last elution is narrow for CZE so that each peak appears very compact, and most small molecules are usually eluted in less than 30 min. If wider separation windows are used, short oligonucleotides can probably be separated.

The addition of cations, such as a cationic surfactant, slows the EOF since the electrical double layer on the fused-silica surface switches to the opposite polarity. Further, an excess of cations, such as metal ions and cationic surfactant, causes reverse flow of the EOF towards the cathode (reverse EOF) (Figure 2b). In CE using fused-silica capillary tubing, the EOF towards the anode (normal flow) increases with increasing pH.\(^{34}\)

Factors affecting separation in CZE have been summarized in an early investigation.\(^{34}\) Nucleic acid bases and nucleosides do not have charges at neutral pH, which presents problems for CZE since EOF is fairly fast, thus the separation of bases and nucleosides is difficult using CZE at neutral pH. However, for the same type of nucleotides having the same number of phosphate groups but different bases, CZE sometimes produces notable resolution, which results in sufficient separation.\(^{35–38}\)

However, the separation of oligonucleotides by CZE is difficult for two reasons: first, the \( m/z \) becomes constant with increasing oligonucleotide length; and second, only a very narrow window size can be used since the EOF is fast when using CZE.

Since oligonucleotides have negative charges on the phosphate group, EPF occurs towards the cathode. A useful method is to slow the EOF, so that resolution of the oligonucleotides would be enhanced. Modifications of the electrophoretic running buffer, such as the addition of urea and a decrease in the pH, expand the CE window.\(^{34,38,39}\)

4.1.2 Micellar Electrokinetic Chromatography

MEKC was established by Terabe et al.\(^{40,41}\) in 1984. In MEKC, partitioning and adsorption to micelles, which are regarded as pseudo-stationary phases of liquid chromatography, act as an effective interaction, as well as EOF and EPF. Thus, even neutral species, that is bases and nucleosides, are potentially resolved by the chromatographic effect. There are two different MEKC methods for nucleotides that have different directions of EOF.

The separation model of nucleotides is shown in Figure 2(c), (d) for cases with EOF towards the anode and towards the cathode. In the presence of an anionic surfactant, such as sodium dodecyl sulfate (SDS), both the micelles and the nucleotides have negative charges, so that less interaction between micelles and nucleotides is expected (Figure 2c).\(^{7,14,42–45}\) In the second case, a cationic surfactant such as dodecyltrimethylammonium bromide (DTAB) is used, and nucleotides interact with cationic micelles by electrostatic interaction (Figure 2d). In this case, EOF occurs in the reverse direction in the presence of an anionic surfactant. Thus, the samples have to be injected from the anode. In addition, nucleotides migrate, with partitioning of nucleotides onto the cationic micelles, which is notably effective since micelles and nucleotides have a different polarity, as well as regular EPF, towards the cathode. In these systems, the capacity factor \( k' \) defined by Equation (5) can be expressed by Equation (6).\(^{34,41}\)

\[ k' = \frac{n_{mc}}{n_{aq}} \]  

(5)

\[ k' = \frac{t_R - t_w}{t_w (1 - t_R/t_{mc})} \]  

(6)

where \( n_{mc} \) is the total numbers of moles of solute in the micellar phase and \( n_{aq} \) is that in the aqueous phase, \( t_w \) is the retention time of the water molecule, \( t_{mc} \) is that of the micelle, and \( t_R \) is that of the analyte. Thus, \( k' \) can be written as Equation (7).

\[ t_R = \left\{ \frac{1 + k'}{(1 + t_w/t_{mc})k'} \right\} t_w \]  

(7)

The resolution (\( R_s \)) between two solutes 1 and 2 is given by Equation (8),

\[ R_s = \left( \frac{H^{0.5}}{4} \right) \left( \frac{\alpha - 1}{\alpha} \right) \frac{k_2}{(1 + k_2)} \times \left\{ \frac{(1 - t_w/t_{mc})}{(1 + t_w/t_{mc})k_1} \right\} \]  

(8)
NUCLEIC ACIDS STRUCTURE AND MAPPING

In summary, the benefit of using CZE and MEKC is that the analytical procedure is simple and preparation of the capillary is not required. Furthermore, CZE has extremely high resolution compared with HPLC.

4.1.3 Capillary Gel Electrophoresis

The separation by CGE is performed in a gel-filled capillary with a sieving matrix such as PAG. Although the m/z of DNA is considered to be independent of the size of oligonucleotide containing more than 10–15 bases, one chain length difference can be detected by the sieving effect at a speed of 1000 bases per hour.

The mechanism of CGE is schematically shown in Figure 4. In capillaries filled with sieving polymer, small nucleic acids move faster through a sieving mesh than large nucleic acids do. The EOF is zero, or very low, in coated capillaries, so that the power supply polarity is the reverse of normal CZE. The gels are covalently bonded or not bonded to the inner surface of fused-silica tubing. The velocity of the nucleic acids through the sieving matrix is mainly dependent on the length of nucleic acid molecules as large nucleic acids migrate slower than small nucleic acids, but also it is influenced by their conformation in some cases. The separation behavior is dependent on temperature, buffer composition, etc.

On the basis of the Ogston model, the relationship between the electrophoretic mobility of the solute (μ) and the gel concentration (T) is expressed by Equation (9),

\[
\ln \mu = \ln \mu_0 - KR T
\]

where \( \mu_0 \) is the migration time in free solution without gel and \( KR \) is the retardation coefficient. The relationship can be applied to CAGE with entangled polymers and has also been experimentally established by means of a Ferguson plot. When the size of the analyte is larger than the mesh size, the electrophoretic mobility

\[ H \]

is the plate number and \( \alpha \) is the separation factor \((k_2/k_1)\).

An example of resolution of oligonucleotides achieved by MEKC is shown in Figure 3. The addition of metal ions improves the resolution of oligothymidine, and the electrophoretic window is expanded with the addition of urea. Further, it has been demonstrated in a few cases that the addition of host–guest reagents improves the resolution of nucleotides only if there was originally a very small difference in CZE and MEKC. For example, nucleotide isomers S'-AMP, 3'-AMP, and 2'-AMP, which have a small difference in their effective m/z, are separated by amplification of the difference in the presence of β-cyclodextrin.

In Figure 4, the model of migration behavior of nucleic acids in CGE such as PAGs is shown. Large nucleic acids migrate slower than small nucleic acids. EOF is zero or less since the fused-silica surface is modified so that samples should be injected from the side of the anode.
is expressed by the reptation mechanism as shown in Equation (10),\(^{(59)}\)

\[
\mu \sim \frac{N}{N_2} = \frac{1}{N}
\]  

(10)

where \(N\) is the molecular size (base unit number of nucleic acids). A refinement on the model at large electric field was achieved by Lumpkin et al.\(^{(57)}\) as expressed by Equation (11).

\[
\mu \equiv K \left( \frac{1}{N + bE^2} \right)
\]  

(11)

where \(K\) is a constant and \(b\) is a function of the mesh size of the polymer network. The relationship has been well established by several experiments.\(^{(10,11)}\)

Although CGE using conventional PAG does not have the ability to resolve differences of sequence, specific base recognition of oligodeoxynucleotides is possible when using polyacrylamide poly(vinyl adenine)-conjugated gel\(^{(60–62)}\) and other types of sequence-dependent polymer.\(^{(63)}\)

### 4.1.3.1 Preparation of Gel-filled Capillary

The preparation of gel-filled capillaries has been extensively investigated.\(^{(64–66)}\) The following procedure is based on these studies.

First, a fused-silica surface may be treated since both a modified and a nonmodified fused-silica capillary can be used for preparation of gel-filled capillaries. Modification of a silica surface is carried out using uncross-linked PAG or by the formation of Si–C bonds, in which EOF is kept close to zero. Further, PAG modified on a silica surface is capable of being cross-linked with PAG that is to be used as the sieving matrix. In this case, the gel-filled capillary is, however, not replaceable.

In order to prepare an inner-surface-modified capillary, an appropriate length (50–100 \(\mu\)m ID) of capillary is rinsed with 1 M NaOH solution for about 15 min and with distilled water for 10 min. Acetic acid solution (6 mM) containing 3-methacryloxypropyltrimethoxysilane (0.4\%) is put into the capillary for 10 min. The capillary is allowed to stand for 1 h and washed with distilled water for 10 min.

To polymerize acrylamide solutions, a stock solution, containing 40\% acrylamide monomer and 0–5\% \(N,N'\)-methylene-bis(acrylamide) as cross-linker, is diluted with buffer solution. The acrylamide solution is degassed thoroughly under vacuum, or by ultrasonic degassing, or degassing with inert gas bubbling. Ammonium peroxydisulfate and \(N,N',N''\)-tetramethylethylenediamine solutions are added into the acrylamide solution and flow into the capillary for 5 min. For gelation, the capillary is allowed to stand for a few hours overnight.

![Figure 5](image-url) Equipment for preparation of PAG-filled capillaries.\(^{(66)}\) [From Figure 1 on p. 1222 in the paper by Y. Baba, T. Matsuura, K. Wakamoto, Y. Morita, Y. Nishitsu, M. Tsuchako, *Anal. Chem.*, 64(11), 1221–1225 (1992). Reproduced by permission from American Chemical Society.]

The gel-filling technique requires careful operation and is shown in Figure 5.\(^{(66)}\) The gel-filling procedure can be problematic because of bubble formation during gel polymerization. This can be avoided when the gel is polymerized at moderate concentrations and the polymerizing acrylamide solution is quickly introduced into capillaries.\(^{(65)}\)

The sieving size of PAG is expressed by the gel concentration (%\(T\)) and the extent of cross-linking (%\(C\)). The definitions of %\(T\) and %\(C\) are given by Equations (12) and (13).\(^{(1,66)}\)

\[
%T = \frac{(\text{mg acrylamide} + \text{mg cross-linker})}{(\text{mL buffer volume})} \times 0.01
\]  

(12)

\[
%C = \frac{(\text{mg cross-linker})}{(\text{mg acrylamide} + \text{mg cross-linker})} \times 100
\]  

(13)

%\(T\) defines the total amount of monomeric material in a given volume of gel, and %\(C\) the relative amount of cross-linker in the monomer content. Cross-linker concentrations of 2–7\% are commonly used. The calibration of the capillaries can be carried out.\(^{(67)}\) Effective ranges of separation of ssDNA and dsDNA at several %\(T\) are 50–1000 bases ssDNA and 100–10000 dsDNA at 3% %\(T\),
shown in Figure 6. The electropherogram detected by UV absorbance is normally contains a high concentration of urea (6–8 M) and 10–1000 dsDNA at 8% of bubbles inside the capillaries. This problem is solved to polymerization-induced shrinkage and the formation gel-filled column is generally tedious and difficult owing In spite of the high performance of CGE with cross-derivatives, act as sieving matrices for DNA molecules. CAGE has additional advantages in the conformational analysis of nucleic acids, especially in the separation of double-stranded nucleic acids.

4.2 Detection Methods

4.2.1 Ultraviolet Absorption Detection

While radioisotopic detection is popular in SGE, it is not easily applied for CE detection. For simple size determination of nucleic acids, UV detection is generally used due to its low cost and convenience. Nucleoside bases have absorption bands around 250–270 nm and their molar absorptivity (ε) is c. 1–1.5 × 10^4 mol^{-1} dm^3 cm^{-1}. Although quantification of nucleotides and size determinations are able to be performed by UV detection, the light path length (25–100 µm) of CE is more than 100 times smaller than that of HPLC (1 cm) so that the theoretical sensitivity of CE is 100–1000 times smaller than that of HPLC. For example, detection limits of concentration of nucleotide in CE, where ε is 1 × 10^4 mol^{-1} dm cm^{-1}, is 1 × 10^{-8} M when 0.001 absorbance unit is the detection limit in the UV detector, while the mole base detection limit using the UV detector is generally reached at 10^{-18} mol of injected DNA. Thus, diluted samples are not very efficiently detected, even though the absolute amount of detection limit is extremely low. This has been a significant problem in CE.

4.2.2 Fluorescence Detection

Laser-induced fluorescence detection is one of the solutions for improving low sensitivity in UV detection. Single molecular detection was achieved for DNA fragments, and detection of native fluorescence was also effective for sensitive detection at neutral pH in CZE and MEKC. Indirect monitoring of nucleotide monomers and ultrasensitive near-infrared (NIR) fluorescence detection in CGE are also useful.
Although most CE analysis for dsDNA has relied on UV absorption for detection, detection by laser-excited fluorescence which is enhanced by addition of some intercalating dyes to dsDNA is also beneficial.\textsuperscript{85,86,91,95} The fluorescence of thiazole orange homodimer (TOTO) (1) and oxazole yellow homodimer (YOYO) (2) is enhanced with intercalating to dsDNA by a factor of 1100 TOTO and 3200 YOYO to that of free TOTO and YOYO, respectively, in which the detection limits are c. 10^{-10} \text{ mol}.

4.2.3 Sequence Analysis

A significant advance in sequencing technology occurred in 1986–87 with the development of Sanger’s method of fluorescent labeling and laser detection. The basic techniques for sequencing were developed originally for SGE\textsuperscript{90,96–104} and the application to CGE had succeeded by 1990–92.\textsuperscript{13–16,105–107} Several types of laser detection systems, including a single spectral channel laser-induced system,\textsuperscript{15} a single-lane with four-channel,\textsuperscript{16} and a four- and two-color channel detection system\textsuperscript{13} using CGE were developed.

The DNA sequencing procedure using four-color sequencing is described as follows. First, target DNA is incubated with primers in the presence of dideoxynucleotides, which are labeled by four types of fluorescence reagent corresponding to four bases, to polymerize the target DNA and terminate the polymerization with dideoxynucleotide.\textsuperscript{108} A mixture of DNA terminated with fluorescently labeled dideoxynucleotides is obtained. Thus, the four-color fluorescence is detected to assign

![Figure 7](https://example.com/figure7.png)
the corresponding bases. Figure 7 shows the structure and fluorescence emission spectra of a set of four-color labeling dyes. Another fluorescence labeling system is also popular, and more recently new types of fluorescence reagents with emissions close to infrared have been developed.

An example of the four-spectral channel sequencing detection system is shown in Figure 8. Two laser beams, 488 nm and 543.5 nm, are combined coaxially through a sector wheel which is rotated at 2 Hz. The fused-silica capillary tubing is placed at the beam focus and the fluorescence is collected and filtered by a filter wheel which is a synchronized sector wheel. The sector wheel is rotated at the same rate as the filter wheel to block the two laser beams alternately. Excitation of 488 nm causes emissions 540 and 560 nm, and excitation of 543.5 nm causes emissions 580 and 610 nm. The detection limits of this detector are 200 zmol for all four types of labeling reagents.

The sequencing technique can be applied to CAGE with noncross-linked polymers. Full automation of the labeling reagents.

5.1 Chemical Structures

5.1.1 Application of Capillary Zone Electrophoresis and Micellar Electrokinetic Chromatography for Nucleic Acid Components

Applications of CZE and MEKC for bases and nucleosides, and charged species nucleotides and short oligonucleotides have been extensively investigated. As an example, separation of bases, nucleosides, and nucleotide monomers was achieved by MEKC with the addition of urea and metal additives, in which even oligonucleotides with 18 monomeric units were resolved. Bases are also separable using several types of CZE methods and applications of CZE to nucleosides in fish tissues have been demonstrated. Determinations of monomeric nucleotides are feasible by CZE, and by MEKC with anionic and cationic surfactants. Using CZE and MEKC, cyclodextrin as a host–guest reagent is useful for molecular recognition of monomeric and dimeric...
Figure 9 Electrophoretic sequencing by CAGE using replaceable linear PAG. DNA sequencing fragments generated on M13mp18 at optimum conditions: 2% 9 MDa linear polyacrylamide mixture and 0.5% 50 kDa linear polyacrylamide mixture, 200 V cm \(^{-1}\), 60°C. Capillary, 45 cm x 0.75 mm ID, coated with poly(vinyl alcohol); running buffers 50 mM Tris, 50 mM TAPS, 2 mM EDTA, 7 M urea; 200 V cm \(^{-1}\) at 60°C; injection: 25 V cm \(^{-1}\) x 10 s. [From Figure 3 on p. 4002 in the paper by O. Salas-Solano, E. Carrilho, L. Kotler, A.W. Miller, W. Goetzinger, Z. Sosic, B.L. Karger, Anal. Chem., 70(19), 3996–4003 (1998). Reproduced by permission from American Chemical Society.]
Figure 10 Schematic of the two-color, confocal-fluorescence capillary array scanner.\textsuperscript{[21]} Excitation light from an argon laser phototube is brought to a 10-µm-diameter focus within the 100-µm-ID capillaries in the array. The fluorescence is passed back through the first beam splitter to a second beam splitter that separates the red and green channels. Sequencing is carried out using conventional two-color dye (FAM and JOE). [From Figure 1 on p. 2150 in the paper by X.C. Huang, M.A. Quesada, R.A. Mathies, \textit{Anal. Chem.}, \textbf{64}(18), 2149–2154 (1992). Reproduced by permission from American Chemical Society.]

The separation of 3’,5’- and 2’,5’-linked adenylyladenosine monophosphate was achieved in the presence of β-cyclodextrin, which has a distinguishable interaction and results in a difference in electrophoretic mobility (Figure 11).\textsuperscript{[46]} This method can be applied for the detection of both linked adenylyladenosine monophosphates in prebiotic products. Even though the separation of oligonucleotides is fundamentally difficult using CZE and MEKC, some trials have been carried out.\textsuperscript{[38,72]}

The methods using CE and MEKC can be applied to analogs of nucleotides such as modified nucleotides.\textsuperscript{[42]}

5.2 Size, Sequence and Conformation Analysis

5.2.1 Size Determination in Capillary Gel Electrophoresis

5.2.1.1 Single-stranded DNA Size determination by CE is best performed by CGE\textsuperscript{[49,63,105,124]} and CAGE,\textsuperscript{[68]} and the first size determination of nucleotides by CGE was demonstrated by Cohen et al.\textsuperscript{[8]} in 1988. The aim was to analyze ssDNA and dsDNA so a comparison of resolution of ssDNA and dsDNA in CE was carried out.\textsuperscript{[70,87]} ssDNA fragments can be separated and detected by UV\textsuperscript{[124]} or laser fluorescence.\textsuperscript{[125]} The separation in sequence analysis of DNA is directly based on the separation techniques of ssDNA. Thus, best resolution is obtained for large DNA with a single base unit.

5.2.1.2 Double-stranded DNA dsDNA has a wider range in molecular size than ssDNA so the resolution of 10 base differences may be required. Highly sensitive detection methods for dsDNA were developed on the basis of the technique, which was improved for SGE.\textsuperscript{[95,126,127]} A detection technique using intercalating dyes has been investigated using CAGE.\textsuperscript{[85,86]} Figure 12 shows the dsDNA by CAGE using HPMC with detection using intercalating dyes.

5.2.1.3 RNA and Nucleotide Analogs The structure of RNA is almost the same as DNA except the hydroxyl group of the 2’-position of ribose in DNA is replaced by hydrogen. Thus, CE, MEKC, and CGE\textsuperscript{[66,128]}
methods are easily applied to RNA since the 2'-hydroxyl group is not important in determining the electrophoretic behavior. For example, application of CGE to transfer RNA and 5S ribosomal RNA has been demonstrated.\(^{129}\)

DNA with linkage of phosphothioate is also able to be separated by similar methods to normal DNA. Successful applications of CGE and CAGE have been demonstrated\(^{130,131}\) and in particular sequencing of antisense DNA analogs is also possible by CGE.

5.2.2 Sequence Analysis by Capillary Gel Electrophoresis

Based on the fundamental studies and further improvement of the instruments, a number of application studies for sequencing nucleic acids have been carried out with electrophoretic conditions such as electric fields,\(^{132,133}\) concentration of polyacrylamide,\(^{75,133}\) etc. Further use of replaceable sieving matrices such as poly(ethylene oxide),\(^{80}\) noncross-linked polyacrylamide,\(^{76}\) poly(vinylpyrrolidone),\(^{81}\) and others\(^{69,134,135}\) is successful for sequencing.

Detection systems have also been investigated to achieve high sensitivity, reproducibility, high speed, and low cost.\(^{136}\) NIR fluorescence,\(^ {94,137}\) labeling dyes,\(^{138}\) and electrophore mass tag dideoxy DNA sequencing has also been developed.\(^ {139}\)

5.2.3 Capillary Array Electrophoresis

To detect a large number of parallel capillaries, several investigations, such as high-speed separation,\(^{140}\) monitoring of 100 capillaries,\(^ {111}\) multiple sheath-flow method,\(^ {110}\) energy transferable primer,\(^ {112}\) multiple laser focusing,\(^ {141}\) and microfabrication,\(^ {142}\) have been carried out. Recently, size analysis of dsDNA using intercalating dyes was also carried out using CAE.\(^ {143}\)

Automation of DNA sequencing is also important for the HGP and has also been developed.\(^ {144}\)
Figure 12 Separation of large dsDNA by CAGE using hydroxypropylmethyl cellulose (HPMC). Operating conditions: HPMC 0.4%, 0.1 M NaCl, 0.54 g Tris, 0.275 boric acid, 0.1 mmol EDTA in 50 mL buffer; 10 or 32 µm ID capillary; 200 V cm⁻¹. (a) 100 base pair ladder, (b) 123 base pair ladder, (c) λ DNA Hind III intercalated with YOYO-3 (a benzoxazolium-4-quinolinium dimer with three carbon atoms bridging the aromatic rings of the unsymmetrical cyanines). [From Figure 8 on p. 214 in the paper by D. Figeys, E. Arriaga, A. Renborg, N.J. Dovichi, J. Chromatogr., A, 669(1–2), 205–216 (1994). Reproduced by permission from Elsevier Science.]

It has been investigated for several types of rapid scanning methods of capillaries, and a detection system using a photodiode array, multipoint detection, and an injection system of samples. Moreover, miniaturization of the system is also important. An electrophoretic system on silicon devices and a miniaturized injection method are also interesting.
5.3 Applications and Needs

5.3.1 Medical

Since CE provides extremely high resolution and rapid analysis, its practical applications have been investigated widely for the HGP, for polymerase chain reaction (PCR) products and restriction fragment analysis. Several modes of CE, namely, CZE, MEKC, and CGE, have useful medical applications, such as AIDS virus (HIV-1) DNA in blood,\(^\text{152}\) antisense DNA using microdevices,\(^\text{153}\) nucleosides in urine,\(^\text{154}\) clinical diagnostic DNA by CZE,\(^\text{155}\) cancer diagnosis,\(^\text{156}\) ssDNA in blood plasma,\(^\text{157}\) DNA restriction fragments in cystic fibrosis and Gaucher’s disease.\(^\text{158}\)

5.3.2 Genetic

Many applications of CE in genetics are possible, such as diagnosis of the detection of point mutation in DNA,\(^\text{159,160}\) gene diagnosis,\(^\text{161}\) restriction mapping,\(^\text{162}\) rat mRNA for gastric H\(^+\)K\(^+\)-ATPase,\(^\text{163}\) plasmid DNA,\(^\text{164}\) and apolipoprotein E genotypes.\(^\text{165}\) ssDNA analysis is beneficial for polymorphism analysis,\(^\text{125}\) and DNA restriction fragments by CAGE,\(^\text{166-170}\) and of the AIDS (HIV-1) virus in blood.\(^\text{171}\) PCR products are able to be analyzed by conventional CGE and CAGE,\(^\text{172}\) and by using a microfabricated device.\(^\text{173}\)

6 LIMITATION AND COMPARISON WITH OTHER METHODS

6.1 Comparison with High-performance Liquid Chromatography

CE, HPLC, and conventional SGE are important techniques for nucleotide analysis and mapping. Comparative studies using several modes of CE and HPLC have been carried out for size determination of large fragments of DNA, and a systematic comparison has also been made using CE and HPLC.\(^\text{148,128,174,175}\)

For the quantification of nucleotide monomers and short oligonucleotides, HPLC is superior to CE in terms of speed and selectivity.\(^\text{176}\) MEKC is similar to conventional HPLC;\(^\text{177}\) for simple analysis of nucleotides MEKC has proven to be superior to HPLC in terms of speed, small sample requirement, selectivity, and sensitivity, in which MEKC is a great time-saving method. Reproducibility of HPLC (1–2%) is somewhat better than CE (2–4%) for the routine analysis of oligonucleotides.\(^\text{128}\)

The resolution power of CGE, which is much superior than that of HPLC, is significant for the analysis of large size DNA fragments. The theoretical plate number reaches over 10 million per meter, which is more than 10 times higher than that of HPLC.\(^\text{16,47,66,109,128}\) CGE has a more rapid separation ability for DNA than for HPLC; for example, CGE was shown to be about four times faster than HPLC for the separation of the same number of DNAs.\(^\text{174}\) Furthermore, the fragmentation of large DNA fragments by HPLC, CGE, and CAGE is equally sufficient for the separation of relatively short nucleotides up to 1000 bases. However, CGE and CAGE are superior to HPLC for the separation of larger DNA fragments.\(^\text{131,178,179}\)

The absolute amount at detection limits of nucleic acids by CE using UV absorption is much smaller than that by HPLC, whereas concentration sensitivity by UV detection of HPLC is about 100 times higher than that of CE. If one can use laser fluorescence detection, the detection limit by CE is much smaller than that by HPLC using UV.

6.2 Comparison with Slab Gel Electrophoresis

CE separations are rapid because of the high electric fields that can be applied, but the throughput is about the same as that of SGE. CAE solved this problem and is almost a prerequisite for the success of the HGP.\(^\text{18}\) Further, CE is superior to SGE on the resolution power, on speed, being easy to fully automate, no preparation of gel, size determination and sequencing of nucleic acids. Comparison of conventional SGE and CGE has been carried out.\(^\text{155,180}\)

6.3 Limitations of Capillary Electrophoresis for Nucleic Acids Analysis

Fragmentation by CE is rapid at a sizing speed of 1000 bases in less than 1 h and CAE is becoming a fully automated technique for DNA sequencing. These techniques are excellent and seem to have great capability for nucleotide mapping, but they have been primarily developed for the goal of the HGP. For example, analysis of relatively small oligonucleotides having 10–20 sequences is not easy using either CGE or CZE. For CGE, highly concentrated and extraordinary cross-linked polymers are required to separate short oligonucleotides. Needless to say, CAE is available as a fully automated instrument, but it is too costly to run only for analyzing short nucleotides. Also, there are less practical methods of CZE and MEKC for the analysis of relatively short oligonucleotides, which are regarded as too large for CZE. As another example, analysis of nucleotides involving unusual linkages, such as pyrophosphate and 2',5'-linked RNA, have been less studied by both CE and HPLC so that CE would be profitable for these analyses.\(^\text{46}\)
Another limitation of CE is that more skill is required to use CE than HPLC and SGE. This is because CE involves techniques that require care to keep high reproducibility, for example pretreatment of a capillary is often required for each analysis and a small amount of impurity sometimes significantly affects electrophoretic behavior in CZE. These problems may be solved by full automation and by using commercially available laboratory kits for CE analysis.

1 INTRODUCTION

There are an increasing number of genomic sequences becoming available. Within the next 5 years even the human genome sequence should be completed. Understanding the meaning of these DNA sequences will take much more work and involve many comparative experiments.

In the past, gene function was defined by comparing a cell containing a specific mutation with a cell that did not have the mutation. Mutations are also used quite effectively for dissecting biochemical mechanisms and pathways. The power of using mutations lies in the fact that a very well defined change is being studied. In the past, most research was confined to model organisms with well-developed genetic systems that allowed gene manipulations. This type of approach is quite useful for experimental organisms that have well-developed genetic systems which allow gene manipulation. It is quite clear that these types of experiments will continue in the future. However, it is also clear that we need to understand gene function in complex organisms where gene manipulation is not possible or easily done.

Comparative studies in the complex genomes are difficult. For instance, it is estimated that there may be over 100,000 genes in the human genome. Of course, there are many naturally occurring mutations that aid geneticists and other researchers to understand disease and other natural processes. However, even putting aside the ethics of manipulating human genomes for experimental purposes, humans are not good experimental organisms because their life span is too long. Hence, it is quite clear that comparative methods focused on complex organisms with long life spans must be independent of gene manipulations. Furthermore, even with “good” experimental organisms, the number of known genes and interactions are too great to be dissected by past methods using conventional recombinant DNA methods. In such experiments, genes are cloned, sequenced, modified and studied in detail out of their native genomic environments.

A large number of methods and variations have been developed for comparing whole genomes and entire repertoires of genes. Most methods can be applied to large and small genomes. The technical difficulty of a particular approach is usually a function of genome size. This article will review genomic comparative techniques, focusing on DD and SH because these methods are most accessible to a large number of researchers.

For simplicity, all calculations done will assume a random DNA sequence composition. However, for many organisms the amount of sequence information available in the databases allows for more accurate calculations of experimental results and for some completely sequenced genomes, a total modeling of the experimental results.
2 OPTIONS FOR COMPARING GENOMES

There are several approaches for comparing, globally, genome structure and function. These studies can be divided into those that compare the primary structure of genomic DNA and those that compare gene expression profiles. It should be noted that gene expression profiling requires quantitative analysis of levels that vary by $10^3$-fold. This means that quantitative studies on gene expression are more complicated than direct genome comparisons.

Gene expression profiling is currently most often done at the mRNA level. Such experiments do not provide information about post-transcriptional regulation of gene expression. Two-dimensional gel electrophoresis has been used for some time to establish and compare protein profiles from different samples. Some recent experiments compare mRNA and protein profiles from the same sample. In yeast, Gygi et al.\(^3\) found little correlation between protein and mRNA expression levels. It will be interesting to see what post-transcriptional regulatory mechanisms are uncovered and how these initial observations are extended to other organisms and systems. These types of comparative experiments and protein profiling in general will not be discussed here.

2.1 DNA Fingerprinting Methods

Genomic sequence comparisons between different samples is the only reliable method to detect all differences. Gene expression profiling can be done using DNA sequencing methodology. In these approaches, random cDNAs are sequenced and the frequency of occurrence of specific sequences is recorded in different cells or under different conditions such as disease states. Some have termed this electronic profiling and several successful biotechnology companies specialize in this approach. These types of experiments form the new field of pharmacogenetics. (Pharmacogenetics promises to tailor treatment and medication to individuals.)

A variation on random cDNA sequencing is called serial analysis of gene expression (SAGE).\(^2\) SAGE links short bits of cDNA sequence together in a single sequencing template to increase efficiency of the analysis. Even so, the financial cost of current technology prevents widespread use of large-scale sequencing experiments for global comparative studies.

DNA fingerprint methods have been used to compare both genomic DNA and cDNA sequences. The first method that was developed hybridized a multilocus simple, tandem repeat probe to restriction enzyme cleaved genomic DNA fractionated electrophoretically.\(^3\) Since then a number of easier polymerase chain reaction (PCR) methods have been developed for DNA fingerprinting. In some cases, PCR is used to amplify unique sequences located between primer sequences composed of arbitrary primers (randomly amplified polymerase chain reaction, RAPD).\(^4,5\) In other cases, the primer sequences consist of interspersed repeat sequences, for example Alu sequences in the human genome.\(^6\) The pool of PCR amplified fragments are size fractionated electrophoretically to create a complex DNA fingerprint. The DNA fingerprints of two or more samples are compared to assess the similarity and differences between samples.

DD\(^7\) compares the size distribution pattern of DNA fragments generated from random amplification of two mRNA samples. Here, we will distinguish cDNA differential display (cDD) from genomic differential display (GDD). A more detailed discussion of these methods is given below.

Methods such as sequencing by hybridization (SBH, also known as DNA chip arrays)\(^8,9\) replace time-consuming electrophoretic size fractionations with a single-stranded DNA array composed of different sequences. Hybridization of a single-stranded sample to a DNA array produces a DNA fingerprint revealing which array sequences are complementary to a position of the sample DNA. In conventional SBH, the presence but not the location of the sequence is obtained. The sample sequence may be reconstructed from the pattern of short oligonucleotides that hybridize to the template. An alternative method, called positional sequencing by hybridization (PSBH),\(^10\) revealed both the presence and location of the complementary sequence. In this protocol, the array targets are partially double stranded and have a single-stranded end. In this format, the single-stranded end of the target sequence hybridizes to the probe element with stacking interactions from the duplex region insuring a high level of matching bases. The specificity of this hybridization may be increased by adding enzymatic steps, such as a DNA ligation and/or polymerase extension reaction.

In SBH, oligonucleotides are typically immobilized in an array format on a silicon chip to which a labeled template is hybridized. The presence of the template on each array element is scored as positive or negative when conventional radioactive, fluorescent or chemiluminescent labels are used.

Conventional SBH experiments have been severely handicapped by the hybridization of mismatched sequences, especially end mismatches. PSBH reduces the level of mismatches at least 10-fold. Further enhancement may be obtained when SBH experiments are analyzed by mass spectrometry (MS).\(^11\) MS analysis does not require a label. MS not only detects the presence of a species as do the other detection methods but also provides the mass of the molecule. Since the masses of the bases are known, different
sequence compositions with distinguishable masses may be distinguished when they are hybridized to the same array element. Potentially, MS allows the experimental results to be precisely correlated to DNA sequence(s).

DNA arrays may also be composed of other molecules. For instance, cloned cDNAs or genomic sequences or even uncloned single or pools of genomic restriction fragments may be used as targets.

Comparative genome hybridization (CGH) experiments hybridize pairs of differentially labeled genomic DNA or cDNAs to normal metaphase chromosomes. Usually, one sample is labeled with fluorescein and the second with 4',6-diamidino-2-phenylindole (DAPI). The samples are mixed together at equimolar ratios. Hybridization to metaphase chromosome means that the DNA probes are sorted to chromosomal regions. The fluorescein/DAPI signal ratio will remain constant unless there is a difference in gene expression. CGH provides a low resolution (~10 Mb) genomic localization of differences and does not provide directly the sequence causing the difference. The advantage is that a controlled pairwise comparison is done, providing a much more robust quantitative analysis. The disadvantage is that the complexities of this method do not allow it to be adapted by a large number of laboratories. A similar type of “two-color” approach has also been applied to analyzing DNA arrays.

### 2.1.1 Isolation of DNA Differences Between Samples

All of the experiments discussed above may be classified as DNA fingerprinting methods. These methods present similarities and differences between samples. An alternative to these approaches are methods that provide information only about the differences between samples.

In SH, only “candidate” differences are provided to the experimenter. An advantage of the DNA fingerprinting methods are that they can be quantitative and provide ongoing information to the experimenter. An advantage of the SH experiments is that they provide directly the candidate differences between samples. The DNA fingerprinting experiments provide information about differences that then must be isolated for further testing. In both approaches, the first chore of the experimenter is to prove that the indicated differences are real. This will allow the level of false differences between samples (i.e. false positives) to be assessed. The level of false negatives (false similarities) between samples is more difficult to assess. Our own approach to this problem has been to verify our method using a model system where the experimental results can be compared with the theoretical results (see below) and where few, if any, differences should exist between samples.

DD and SH are technically demanding. The key to success lies in understanding the underlying biochemistry and biophysics. The goal of this article is to provide the user with a basic understanding of the principles of these methods and factors that affect reliability. Also discussed are some of the many options and applications.

### 3 DIFFERENTIAL DISPLAY

#### 3.1 Principles

DD was originally developed by Liang and Pardee as a PCR method for amplifying and labeling subsets of mRNA to identify differences in gene expression. A recent useful collation of a variety of DD articles can be found in Liang and Pardee. The pool of amplified products <500 bp (base pairs) is size-fractionated on a high-resolution DNA sequencing gel. This produces a display consisting of the size-dependent banding pattern of the pool of PCR products. The display produced from two or more samples is compared to identify differences in gene expression patterns.

In the originally described method, the starting material was purified mRNA which is converted to cDNA using conventional methods. Then PCR was used to amplify subsets of the cDNA library. One of the PCR primer pairs was complementary to the polyA tail of eukaryotic mRNA with additional 3'-anchor bases (e.g. 5'T<sub>11</sub>CA<sub>3</sub>). The use of a homopolymer T primer with a unique dinucleotide 3'-end serves two purposes. First, the unique dinucleotides anchored the primer to the unique genomic sequences adjacent to the 5'-end of the polyA mRNA tail. This insured the polymerase extension reaction initiated at the sequence adjacent to the polyA tail and not randomly within the mRNA polyA tail. The anchor bases also control the complexity of the PCR amplification products. Twelve different dinucleotide (e.g. CA, CT, GC, GA, GT, GG, GC, AA, AT, AG, AC) anchors are needed to amplify all mRNA specifically. In a random sequence, a dinucleotide anchored primer sequence would reduce the number of PCR amplification with a specific dinucleotide anchor products by 1/12.

The second PCR primer was a 10-mer composed of an arbitrary sequence (e.g. Ltk3, CTTGATTTGCC). There are 1049 different possible 10-mer combinations and any one 10-mer sequence would be expected to occur once in 10<sup>8</sup> bp. Since an average mRNA is about 10<sup>3</sup> bp in length, a single 10-mer should hybridize to 1 in 10<sup>3</sup> cDNAs.

DD analysis is usually restricted to fragments less than 10<sup>2</sup> bp, hence the number of amplified products should be even less. The arbitrary primers used in these experiments

### 3.2 Applications

DD has been applied in a variety of research, including the following:

- **Genetic Disorders**: Identifying genetic markers associated with disease.
- **Cancer Research**: Differentiating normal and cancerous tissue.
- **Pharmaceutical Research**: Identifying drug targets.
- **Environmental Studies**: Monitoring changes in gene expression due to environmental stress.

## Reference

## Discussion

DD and SH are both powerful methods for identifying gene expression differences. They are particularly useful in studies where a large number of samples need to be compared, such as in cancer genomics or in the study of environmental stress responses. However, they are also challenging and require careful experimental design and analysis. It is important to consider the potential pitfalls and limitations of these methods when applying them to a research question.
were chosen after testing to give reproducible and specific amplification products with the polyT anchored primers. Subsequent studies have taken a more critical look at the theoretical distribution of primers so that the speed and efficiency of DD could be maximized.\(^{(19)}\)

### 3.2 Options

#### 3.2.1 Genomic Analysis

Genomic comparisons of simple genomes may be done directly. For instance, it is quite easy using pulsed field gradient (PFG) techniques to compare chromosomal fingerprints of small genomes like bacteria, yeast and protozoa.\(^{(20)}\) The resolution of these methods can be improved by establishing fingerprints using restriction enzymes that cleave infrequently and in some cases restriction enzymes that cleave frequently. These types of approaches can be applied to organisms whose genomes range in size up to about 100 million bp. In contrast, the human genome is 1000-fold greater than this. With today’s technology it is still impossible to compare directly total human genomes. Instead genome complexity must be reduced.

We\(^{(21–25)}\) and others\(^{(26–28)}\) have reported on the use of targeting in DD. In this approach, a class of fragments containing a specific sequence (a target sequence) is selected for analysis (see below). In contrast to others, our methods have focused on analyzing selected genomic fragments rather than cDNAs (targeted genomic differential display (TGDD) vs targeted cDNA differential display (TcDD) respectively). The focus on genomic DNA allows for an exact modeling of the expected results using DNA from genomes whose entire sequence is known and was easier to develop as a quantitative method because of the smaller dynamic range requirements (e.g. \(10^0\)–\(10^5\)-fold for genomic vs cDNA studies, respectively).

Two methods for TGDD were established by us.\(^{(29)}\) In both methods, oligonucleotides of known sequence are ligated to the ends of genomic restriction fragments. In Method I, there is an initial hybridization – capture step which is used to purify the restriction fragments that contain the target sequence away from the remaining restriction fragments. An immobilized oligonucleotide complementary to the target sequence is used for the hybridization – capture step. Subsequently, the captured fragments are amplified by PCR. A single PCR primer complementary to the adapter sequences ligated onto the ends of the genomic fragments may be used. Alternatively, the adapter primer may be used with a primer complementary to the target sequence. In the former case, sequences from each side of the target are amplified; in the latter case the sequence from only one side of the target is amplified.

Method I eliminates the capture step and uses long (40-mer) adapter primers to enhance self-annealing of the adapter primers, an effect called PCR suppression.\(^{(30)}\) In this method, a primer to the target sequence and a short 20-mer primer to the adapter sequence are used. Only fragments that contain a target sequence can be amplified. This version of the method has the advantage that it is easier to perform. Although, the adaption of interspersed repetitive element-bubble PCR\(^{(31)}\) with Method I should prevent self-annealing of the adapter sequences.

Targeting has been adapted to cDNA studies (Nguyen et al., unpublished results). In TcDD, the adapter primer was replaced by a primer complementary to the polyA tail.

#### 3.2.2 Targeting

A detailed discussion of targeting issues can be found in Bouchard et al.\(^{(29)}\) In brief, it is important to realize that targeting can be done with a simple repeating sequence (the polyA tail of eukaryotic cDNA is one example of this) or more complicated sequence coding for a protein motif, a cis-acting sequence such as transcriptional activation signal. The method can analyze the target sequence itself and/or the surrounding sequence depending on the PCR primer that is used. Usually, the target is interspersed throughout the genome. This means that the method samples sequences spread throughout the genome. In some cases the target may be more confined to a specific chromosomal region, for example telomeric sequences.

In the case of simple repeating sequences, unique bases added to the 3′- or 5′-end of the primer serves to anchor the primer to the target end and to reduce complexity (see above).

The question of how to design more complex motif primers that target gene families is not yet answered. Most, if not all, gene families consensus sequences were developed comparing amino acid compositions and not DNA sequences. In fact, very little work has been done on characterizing gene families at the DNA sequence level because it is clear that there can be much more variability at the DNA sequence level because of the redundancy of the genetic code. Additionally, different preferential codon usage is observed in different organisms and an emerging complication is that codon usage in a particular species may reflect the expression level of the protein sequence and/or be protein class specific.

### 3.3 Trouble Shooting

The major problem with DD experiments is the high number of false positives. A suggested way of dealing with this issue is to reconfirm each alleged difference individually by hybridization. This requires that the
DNA fragment be isolated and/or sequenced so that a hybridization probe can be generated.

Our own experience with TGDD has suggested several ways of improving the experimental results. One of the most important factors is to analyze high-resolution Gaussian-like distributions of the fragment size fractionations. In most DD experiments, the sample is radioactively labeled and the fractionation results recorded by exposure of the polyacrylamide gel to film to produce a banding pattern. Although this type of analysis is useful, especially if the focus is kept on the differential presence of very dark bands, a much more realistic pattern of intensity changes is obtained when higher resolution data are collected in real time on an automated DNA sequencing instrument.

Our extensive characterization of the factors that influence the reliability of DD has led us to the conclusion that the most important aspect is to match the starting DNA concentrations. There are several reasons for doing this; in particular, the occurrence of unequal amplification of the PCR product during the late cycles. This problem is likely related to the specific sequence that needs to be amplified. For example, although the human genome is 60% A + T, usually equal amounts of the trinucleotide precursors are added to the PCR. This may mean that in each cycle of PCR there is a 20% difference in the use of trinucleotide precursors dATP and TTP vs dCTP and dGTP. Furthermore, the Michaelis constant ($K_m$) of each trinucleotide is different. Hence, the cycle at which precursors become limiting will differ. Of course, this is only a theoretical consideration. The real inequities must be based on the base composition of each fragment in the amplified pools. Another cause of unequal amplification may be the rapid annealing of high concentration PCR products, which would then prevent the subsequent annealing or extension of primers. These considerations emphasize the importance of using samples with matched DNA concentrations and a low number of PCR cycles.

Another consideration in any experiment involving nucleic acids, and especially those involving DNA, is the accurate determination of the sample concentration. It is difficult to accurately determine DNA concentrations. In the cell, 90% of the nucleic acid is RNA. This means that the greatest detriment to accurately determining DNA concentration from a cell extract is contaminating RNA sequences. Although it is possible to purify DNA from RNA via density gradient centrifugations, this is not usually done because of the limiting amount of material that is available. RNA or DNA specific dyes can be used but they will bind to the alternative species with less affinity as pointed out by many of the manufacturers. The problem is that the amount of contaminating material is unknown. Hence, it is more useful to be consistent in the manner in which DNA concentrations are determined and correlating this with useful results. In fact, since the entire scientific community has this problem it might be best to try several initial (two-fold variations below and above the target) DNA concentrations. Additionally, one might consider varying the number of PCR cycles by two cycles around the target to minimize the number of experiments needed, especially when starting out.

An important issue that cannot be ignored is the ratio and concentration of the primers in the PCR. For small oligonucleotide primers, the annealing temperature will be concentration dependent in addition to being sequence dependent. Other considerations in these types of multilocus are the frequency of occurrence of particular sequences in the template DNA as well as the sequence conservation. The best way to handle these variables is to determine the best ratio and concentration of primer pairs to use empirically. Typically we titrate multilocus primers against each other in the 0.3 to 2 mM range.

### 3.4 Applications

There are many applications for DD and an increasing number of publications are appearing using this technology. Most publications focus on cDNA applications. Our own studies using TGDD on closely matched genomes compare the genomes of twins, families and different tissues from the same individual. The goal of these experiments is to determine the effect of genome stability and heritability on phenotype.

### 4 SUBTRACTIVE HYBRIDIZATION

#### 4.1 Principles of Subtractive Hybridization

The goal of SH experiments is to isolate a target sequence(s) (T) that is present in one sample, called the test DNA (S), and absent in a matched sample, called the driver DNA (D). There are a large number of published protocols. In all cases, a mixture of excess D mixed with S, is denatured and allowed to reanneal. In this reaction there are three single-stranded species which can be distinguished as shown in Figure 1.

The D and S DNAs can form parental homoduplexes or heteroduplexes with complementary strands. All

![Figure 1 Single-stranded DNA.](image-url)
sequences are in common except for the T DNA. The T DNA can only form homoduplexes (Figure 2).

Equation (1) describes the kinetics of double-stranded DNA formation:

\[ f_{ds} = \frac{k_2 C_0 t}{1 + k_2 C_0 t} \]  

(1)

where \( k_2 \) is the second-order rate constant, \( C_0 \) is the initial concentration of single-stranded DNA segments, and \( t \) is time. The fraction of DNA that has formed double strands, \( f_{ds} \), can be calculated from the initial concentration as shown in Equation (2):

\[ C_{ds} = f_{ds} C_0 = k_2 C_0^2 t \]  

(2)

When this equation is applied to SH, two DNA samples must be considered. The first sample contains S- and T-type DNA; the second sample, D, contains only S-type DNA. Since T strands will only form double strands with other T strands the concentration of T: T, denoted \( C_{Tds} \), can be determined from Equation (2). Equation (3) shows:

\[ C_{Tds} = \frac{k_2 C_0^2 t}{1 + k_2 C_0 t} \]  

(3)

The formation of S:S, S:D, D:D can be determined by considering the kinetics of D:D formation and then extracting the amount of S:S formed from the mole fraction of S:S, \( X_{S:S} \) (see Equation 4). This can be done under the conditions where the concentration of S is negligible compared to the concentration of D.

\[ X_{S:S} = \frac{C_{S:S}^2}{C_{D:D}^2} \]  

(4)

where \( C_{S:S} \) and \( C_{D:D} \) denote the initial concentrations of S- and D-type strands respectively.

Equation (5) shows

\[ (C_{S:S}) = (C_{D:D}) \times X_{S:S} = \frac{k_2 C_{D:D}^2 t \times C_{S:S}^2}{(1 + k_2 C_{D:D} t) C_{D:D}^2} \]

\[ = \frac{k_2 C_{S:S}^2 t}{1 + k_2 C_{D:D} t} \]  

(5)

After the hybridization the next step is enrichment by PCR. Only the T:T and S:S strands have matching primers so only those strands will be exponentially amplified. This effectively removes S:D and D:D strands reducing the amount of S contaminants and enriching the amount of T strands. The ratio of enrichment resulting from the first subtraction round is given by Equation (6):

\[ E = \frac{(C_{Tds})}{(C_{S:S})} = \frac{(k_2 C_0^2 t)}{(1 + k_2 C_0 t)} \times \frac{(1 + k_2 C_{D:D} t)}{k_2 C_{S:S}^2 t} \]

\[ = \frac{(C_T^2)}{(C_S^2)} \times \frac{(1 + k_2 C_{D:D} t)}{(1 + k_2 C_{T} t)} \]

(6)

Since the T and the S strands come from the same genome they have the same concentration. Under this assumption the enrichment effectively simplifies to Equation (7):

\[ E = \frac{(C_{Tds})}{(C_{S:S})} = \frac{C_{D:D}}{C_T} \]

(7)

Therefore the enrichment ratio is increased or the amount of contaminating S strands is decreased simply by using a much higher concentration of D strands relative to T.

4.2 Options

Many variations and “improvements” on the SH concept have been published. Despite this, routine success has been elusive, although it is becoming more frequent. The major improvements in the technology included a minimization and simplifying the number of manipulations, use of PCR amplification, and developing more effective protocols through an improved understanding and modeling of the hybridization kinetics of a variety of approaches.

4.2.1 Polymerase Chain Reaction Subtraction

A commercial SH kit sold by Clontech is called “PCR-Subtraction”. The principles but not the details of this procedure will not be presented here. (Details of this protocol can be found in material available from Clontech.)

This protocol was developed from modeling experiments of a variety of SHB protocols. The authors considered several protocols: double-stranded DD and double-stranded SS (+TT); double-stranded DD and complementary single-stranded S (+T); single-stranded D and double-stranded SS (+TT); single-stranded D and complementary single-stranded SS (+TT). The initial modeling experiments focused on cDNAs and a single cycle protocol was developed. This method, called PCR subtraction, allows differential expressed genes to be isolated in a single round of subtraction for complex genomes and genomic differences to be isolated for microorganisms of genomes less than 10 Mb (Figure 3).
In this protocol, first denatured 3 g D and 0.1 g S (+T) DNAs are annealed together in 1.5 L for 20 h at 68 °C. This allows an approximate equalization of the differentially expressed genes in the single-stranded fraction because of the second-order hybridization kinetics of the different cDNA abundance classes. In practice, two simultaneous initial SH reactions are carried out. The only difference in the reactions is that the S DNAs have different adapter sequences ligated onto their 5'-ends. The 5'-ends do not have a ligated adapter sequence because double-stranded unphosphorylated adapters were used. No adapters are ligated onto the D samples. The two reactions are mixed together and added, undenatured, to a new fraction of denatured D. During the second hybridization, the fragments shared between D and S are reduced further. The single-stranded T fragments in the two reactions will now form a TT with different 5'-end sequences. In a subsequent PCR the ends are filled in. Only duplexes with unmatched ends are amplified because the homoduplexes with complementary adapters self-anneal and preventing annealing of the shorter PCR primers, a phenomenon called suppression PCR.\(^3\) This method takes advantage of rapid annealing of T DNA relative to the remaining S DNA in the single-stranded fraction.

4.3 Trouble Shooting

The major nonobvious difficulties in SH experiments, are similar to those encountered in DD experiments. Many of the problems can be alleviated by careful attention to DNA concentrations. However, a major difficulty is the assessment of DNA concentrations that are extremely critical and may best be handled empirically, especially when getting started.

4.4 Applications

There are many applications of SH experiments and progress is being made in identifying cDNAs differentially expressed. The major problems that need to be resolved are how to detect single base pair differences between samples and how to carry out total genomic subtraction experiments. In fact, more complex protocols have been developed using a complex reduction protocol with a gel electrophoresis step called in-gel competitive hybridization (IGCH)\(^{36–38}\) and/or a preferential PCR amplification step called representational difference analysis (RDA).\(^3\) In IGCH, excess D and T are mixed together, denatured and then fractionated using high-resolution electrophoresis. Individual size fractions are isolated from the gel and allowed to anneal.

5 OTHER CONSIDERATIONS

Most genome comparative experiments are not done on single cells because of the added difficulty of working with small amounts of DNA and in the case of genomic DNA, two molecules. Hence, the results present an average of several and usually, many cells. It is clear that it would be valuable to develop comparative methodology that allows the analysis of single cells. For instance, the analysis of single cells making up a tissue would provide information on the range of changes occurring in a tissue rather than the average of the changes.

There are several methods that can use the PCR to amplify DNA from low copy, including single molecules. One of the first methods was primer extension pre-amplification (PEP).\(^4\) Reasonable success was reported with a primer pool of length \(n = 15\), containing every possible 4\(^{15}\) primer. The concentration of any unique species is extremely low, but apparently high enough to insure amplification (e.g. 30 cycles) of most (estimated to be \(\sim 80\%\)) of the genome after 50 cycles of PCR. A major
problem with this method is the potential for the primers to interact with each other.

An improvement to this method used a chimeric primer, with a variable portion and a conserved portion. This method was called tagged polymerase chain reaction (T-PCR)\(^{(41)}\) because genomic fragments were tagged with a common adapter sequence during the PCR. In T-PCR, each primer had a 5′-end with a constant 17 base sequence and a 3′-end with a variable 9 base sequence. The first few rounds of PCR were done with the chimeric primer, then this primer was removed and the remaining PCR cycles were done with a primer solely composed of the constant region located at the ends of the tagged amplified fragments. A number of variations were developed, such as degenerative oligonucleotide-primed polymerase chain reaction (DOP-PCR).\(^{(42)}\) Here the primer contains an internal variable portion (9 bases in length), a long 5′ constant region of 13 bases in length and a short 3′ constant region (3 bases in length). Cheung and Nelson\(^{(43)}\) demonstrated that, with a slight modification, DOP-PCR could be used to amplify random genetic markers from small amounts of DNA.

6 PERSPECTIVE

Comparative genomics is a rapidly changing field. Perhaps the most important aspect in the application of a specific technology is adaptability. Not only is it important to stay advised of critical improvements in methods and conceptualization that create quantum improvement in the technology, but it is also important to be able to adapt new technologies as they become available.

The question of how one decides on a specific approach is more difficult. DD does not, in general, provide sequences of interest but rather shows you where they are so they may be isolated. DD provides quantitative information on the number and the extent of differences. The end results of an SH experiment are the sequences of interest. However, SH does not provide information about the number or the level of differences.

DNA Molecules, Properties and Detection of Single

Zhifeng Long
Genetic Therapy, Inc., A Novartis Company, Gaithersburg, USA

1 Introduction

The ability to detect deoxyribonucleic acid (DNA) molecules is crucial to the development of molecular biology and today’s many analytical instruments for biological applications. From the beginning of the molecular biology era, the search for better ways to detect DNA has never stopped. Such endeavor has led to enormous advances in our understanding of DNA – the basic building block of life. It was the improvement in X-ray diffraction that generated the crystallographic data for DNA and formed the basis of the classical discovery of the double helix structure by Watson and Crick. It was the DNA polymerase chain terminator sequencing method that allowed us to read the genetic make-up of life and revolutionized the field of automated sequencing. It is the polymerase chain reaction (PCR) that makes DNA detection, cloning and sequencing so easy and so powerful.

Technological advances have created more DNA detection systems with more power than ever before. By amplifying the target or its molecular counterpart, the probe, very minute amounts of DNA can be detected or even sequenced. Different technologies give rise to different DNA detection systems. Each system has its merits and limitation. In many applications, detection sensitivity is the parameter of interest. This article first gives an outline of different DNA detection systems and their sensitivities and limits. It then describes how to achieve and prove one-copy sensitivity. Finally, it discusses the testing strategy, supported by statistics to increase detection confidence. Although the limit of detection (LOD) can be improved with better technology and instrument, the highest sensitivity is set by probability laws. To detect one-copy of a DNA molecule, one needs to understand the properties of single.

2 CURRENT TECHNOLOGIES OF DNA DETECTION

2.1 Principles

Nucleic acid probes interact with their complementary target sequences mainly through H-bonding. We call such an interaction molecular hybridization. Molecular hybridization between probe and target sequences is the basis for most current technologies of DNA detection. Mass spectrometry (MS), which detects DNA by separating ionized molecules according to their ratios of mass to electric charge, is an exception. There are direct and indirect detection methods. Direct detection usually involves an excessive amount of target DNA and specialized instruments or methods that detect DNA without modifying the original quantity. In many applications, however, the limited amount of target DNA prohibits direct detection. In this case, indirect detection involving either probe or target DNA amplification can be used to enhance the signal of the probe or target.
DNA can be detected directly by a number of methods and instruments. Using a spectrophotometer with ultraviolet (UV) capability to measure optical absorbance (OD) at 260 nm, it is possible to detect DNA in aqueous solution (OD) at a concentration of 250 ng mL$^{-1}$ and above. For accurate measurement, however, a concentration of 1 µg mL$^{-1}$ or higher is preferred. Ethidium bromide (ETBr) forms a noncovalent complex with double-stranded DNA by intercalating between stacked base pairs. Upon UV illumination, the DNA–ETBr complex emits an orange fluorescence which allows the detection of DNA. This is usually used in conjunction with agarose or polyacrylamide gel electrophoresis (PAGE). DNA is first separated based on size by gel electrophoresis, then the DNA in the gel is visualized by staining with ETBr and illuminated with a UV transilluminator. Photographs of stained gels showing DNA bands are often taken with a Polaroid camera. As little as 10 ng of a 300 base pair (bp) DNA can be detected in this way. Using the molecular hybridization technique, one can transfer the DNA bands from agarose gels to a solid membrane and use a DNA as a probe to detect another DNA that has a homologous sequence.\(^7\)

Both DNA and RNA molecules can be detected by molecular hybridization. Nucleic acid samples can also be spotted directly on a solid membrane and such a method is called dot blot or slot blot, depending on the way in which the sample is applied to the membrane. The probe can be labeled radioactively or nonradioactively, providing a means for detection following molecular hybridization. The molecular hybrid is visualized with the aid of an X-ray film when radioactive or chemiluminescence labeling is used, or by colorimetric detection of biotin/alkaline phosphatase–streptavidin conjugate.\(^8\) As little as $10^6$ copies of a DNA or RNA sequence can be detected by molecular hybridization methods. Subpicomolar levels of DNA can be detected directly with a mass spectrometer. However, it cannot distinguish a target-specific sequence in a sample containing mixed DNA molecules.

In addition to direct detection of DNA, there are indirect detection methods that involve amplification of either the target DNA or its probe. The most widely used target amplification technology is the PCR.\(^3\) It is possible to detect one DNA molecule by PCR amplification.\(^6\) Among a number of probe amplification techniques, the branched deoxyribonucleic acid (bDNA) system is the most successful.\(^9\) It is possible to detect as few as 50 molecules with bDNA technology.\(^10\)

Molecular hybridization has been widely used in screening DNA libraries in colony and phage plaque hybridization in recombinant DNA laboratories.\(^11\) Traditional recombinant DNA applications include bacterial colony and phage plaque screening, plasmid DNA screening by agarose gel and/or Southern blot hybridization. Recent additions include in situ hybridization and fluorescence in situ hybridization (FISH), microarray or gene chip technology, DNA fingerprinting and its forensic applications. There are commercial kits based on DNA hybridization, including diagnostic kits for viral infection, cancers and inherited genetic mutations. More sophisticated diagnostic tools have entered the market in recent years, which involve amplification techniques such as PCR and bDNA. These usually require special equipment and/or expertise. DNA sequencing technology has now become a basic tool, not only for molecular biology, but also for many far-reaching projects such as the genome projects of human and other species. It is has also been used as a detection method in genotyping and pharmacogenetics.

### 3 PARAMETERS AFFECTING DETECTION SENSITIVITY

The methodology, the size and concentration of the target DNA and the levels of complexity and impurity of the test matrix can all affect the sensitivity of a detection system.

#### 3.1 Definition of Sensitivity

A clear definition of sensitivity is essential for comparing one assay with another. A sensitivity unit should define both the lowest concentration of the target and the level of impurities in a test matrix in which the target is present. Often the target is a short stretch of DNA sequence and the test matrix is an aqueous solution of DNA of high complexity, such as genomic DNA. Thus, detecting one copy of the target DNA in $10^6$ copies of genome of an organism is more sensitive than detecting one copy of the target DNA in $10^3$ copies of the same genome because the former has a higher level of impurities than the latter.

#### 3.2 Detection Method

The methodology often presets the upper limit of sensitivity of a detection system. The spectrophotometric method using OD at 260 nm detects only down to 250 ng mL$^{-1}$ DNA. MS can detect subpicomolar levels of DNA, or a few hundred molecules in 0.1 µL, since this technique can use very little amount of sample. Although quick and direct if one has access to the equipment for these two techniques, neither of them can detect a sequence-specific target in a sample containing different DNA molecules. Agarose gel electrophoresis or PAGE can separate different DNA molecules by size,
and detect as little as 10 ng of DNA by ETBr staining. Combining agarose gel electrophoresis with Southern blot hybridization will increase the detection sensitivity to 10^5 molecules with very high specificity provided by the molecular hybridization with a sequence-specific probe.

To compare different methods more easily, we shall convert the mass of DNA into molar concentration. Assuming that the DNA target is a 300 bp fragment, it is interesting to find that 10 ng contains 3 \times 10^5 molecules. The size of DNA is in reciprocal relation to the number of molecules; for the same mass, the larger the DNA fragment, the smaller is the number of molecules.

The sensitivity and specificity of an indirect, amplification-based detection system is usually higher than that of a direct DNA detection method. The bDNA technique can detect as little as 50 molecules of a target-specific sequence in 500,000 human cells or 10^6 copies of human haploid genome. This sensitivity, if calculated for the mass ratio, is equivalent to detecting a target-specific sequence in 500,000 human cells or 10^6 sequences. PCR can detect as little as one molecule of target-specific sequence in a sample containing different techniques can detect as little as 50 molecules of a fragment, the smaller is the number of molecules. The size of DNA is in reciprocal relation to the number of molecules.

### 3.3 Size of DNA

Depending on the method of the assay, the size of the target DNA may or may not affect the detection sensitivity. Spectrophotometry and agarose gel electrophoresis may detect 250 ng mL\(^{-1}\) and 10 ng per band, respectively, regardless of the size of DNA. Since the size of DNA is in a reciprocal relation to the number of molecules for the same amount of DNA, these methods have a higher sensitivity in detecting larger size DNA when the sensitivity is expressed as the smallest number of molecules detected. On the other hand, PCR is less sensitive in detecting large-size DNA because it is less efficient in amplifying larger DNA fragments. In detection systems based on the TaqMan\(^\circledR\) chemistry described below, it is desirable to choose a product size of 100–400 bp for optimum PCR amplification. However, it has been shown that PCR can detect one copy of a 1.4 kilobase (kb) DNA sequence in 10^6 copies of the human haploid genome, using the conventional gel electrophoresis and Southern blot hybridization method.

### 3.4 Assay Optimization

It is relatively easy to optimize the detection conditions for direct detection methods. In spectrophotometry, an instrument that uses the least sample volume gives the highest sensitivity. Some current models of spectrophotometers can measure OD in a sample volume as small as 50 \(\mu\)L. Some models use a 96-well format quartz microtiter plate, offering both high throughput and sensitivity. A 50 \(\mu\)L volume of DNA at 250 ng mL\(^{-1}\) concentration contains only 12.5 ng of DNA. This sensitivity is equivalent to detection by agarose gel electrophoresis, although a more accurate OD measurement requires a DNA concentration of 1000 ng mL\(^{-1}\) or 50 ng of DNA in 50 \(\mu\)L.

PCR assay optimization involves both the amplification and postamplification steps. In assays that use agarose gel electrophoresis to detect PCR-amplified products, it is important to include the limitation of detection by gel electrophoresis. The smallest amount of DNA that can be detected in an ETBr-stained agarose gel is approximately 10 ng. As shown above, 10 ng of a 300-bp DNA fragment contains 3 \times 10^9 molecules. It requires a minimum of 37 cycles of PCR to amplify one molecule to 3 \times 10^10 molecules (assume 100% amplification efficiency). Let \(x\) be the number of PCR cycles required to increase the target sequence by 3 \times 10^10 fold, then we have \(2^x = 3 \times 10^{10}\). Solve the equation to obtain \(x \approx 35\). Since it takes two cycles to generate the first double-stranded PCR product bracketed by two PCR primers, it requires \(n = 35 + 2 = 37\) cycles of PCR to amplify one molecule to 3 \times 10^{10} molecules). This is very important information, because it tells us that unless we run 37 cycles of PCR we should not expect to see the target band in an agarose gel. Very often it is necessary to run more than 37 cycles to achieve one-copy sensitivity, because the amplification is rarely 100% efficient.

#### 3.4.1 Real-time Polymerase Chain Reaction Detection of a Single DNA Molecule: One Example

The fluorescence detection of PCR product using the 7700 Sequence Detection System from PE Biosystems (Foster City, CA, USA) allows real-time detection and quantitation of DNA sequences without the need for labor-intensive processes such as gel electrophoresis and radioactive hybridization. The 7700 instrument has a built-in 96-well format thermal cycler. The detection is based on the TaqMan\(^\circledR\) chemistry. The method uses a fluorescence oligonucleotide probe with a 5' reporter dye and downstream 3' quencher dye. During PCR, the 5' \(\to\) 3' exonuclease activity of the Taq DNA polymerase releases the reporter, whose fluorescence can then be detected by the laser detector.
of the 7700 instrument. Using this system, a 417-bp sequence of the \textit{Herpes simplex} virus thymidine kinase gene (HSV-Tk) was amplified using primers 5'-CGAGACAATCGCGAACATCTAC-3' (forward) and 5'-GCCAGCATAGCCAGGTCAAG-3' (reverse) and a TaqMan® probe, 5'-FAM-CCGGCACAAACATCGTGT-TAMRA-3', that contains a covalently linked reporter dye FAM at the 5'-end and quencher dye TAMRA at the 3'-end. It has been shown that as little as one copy of the HSV-Tk gene can be detected in a background of 3.3 µg of genomic DNA, which is equivalent to 500,000 human cells.\(^{12}\)

As shown in Figure 1(a–c), detection of one copy of DNA requires more than 45 cycles of PCR amplification using the PE 7700 system. To evaluate the results obtained with this real-time PCR, the amplified products were analyzed on agarose gels, followed by Southern blot hybridization. The presence or absence of hybridization for all of the reactions matched completely the results from the 7700. Differences between the intensities in

![Amplification plots and hybridization results for (a) 0-, (b) 1- and (c) 10-copy of targets using the PE 7700 sequence detection system.](image-url)

\(\Delta R_n\) is plotted vs time (PCR cycle number). (a) Four replicates of 3.3 µg of negative DNA (0 target); (b) six replicates of one target per 3.3 µg of DNA; (c) four replicates of 10 targets per 3.3 µg of DNA. The horizontal solid line spanning each plot depicts the threshold fluorescence intensity (0.013). Any sample that reached a fluorescence value that exceeded the threshold was considered to be positive, and the cycle at which this first occurred was defined as the threshold cycle \((C_t)\). A sample for which no amplification occurred is given a \(C_t\) value of the total number of PCR cycles (60) performed. The isotopic Southern blot hybridization results of the amplified products at the end of the 60 cycles are shown in the insets, with the \(C_t\) values given. (Reproduced by permission of Eaton Publishing from Lockey et al.\(^{12}\))
hybridization signals and the threshold cycle \((C_t)\) values were probably caused by nonexponential amplification in the later cycles of PCR after the threshold. At a concentration of 10 copies per sample the \(C_t\) values of different samples were very close (43.3–43.9), but the intensities of hybridization signals varied significantly. This suggests that the use of \(C_t\) values for quantitation is more accurate than analyzing the product yields at the end of all PCR cycles. The former measures at the logarithmic phase of amplification. \(C_t\) values vary widely in the replicates of the one-copy samples. This suggests that quantitation is no longer accurate at such a low concentration. In other words, it is possible to detect one copy of DNA, but not possible to quantitate it by PCR. Unlike the detection of DNA in samples containing 10 copies of target molecules, detection of DNA in samples containing one copy of the target is not a 100% event. This will be discussed further later.

With proper assay development and validation, the PE 7700 automated amplification and detection system is able to achieve reproducibly one-copy sensitivity without the need for a time-consuming assay development process and highly experienced staff to analyze PCR products, making it an ideal system for clinicians and researchers who demand a high-throughput PCR assay. The method has been adapted to detect infection in patients treated with living pig tissues. With the inclusion of a calibration curve based on known concentrations, it can be used for both high-sensitivity end-point detection and quantitation within one test.

### 3.5 Levels of Noise or Impurities of the Test Matrix

The presence of impurities in a test sample may affect the specificity and sensitivity of the detection system. The OD method using spectrophotometry is greatly limited when impurities exist in similar amount to the target DNA, even if the impurities are not nucleic acids. The OD method is unable to detect the target sequence in the presence of other nucleic acids. For detection systems based on molecular hybridization, including PCR, it is possible to detect a target sequence in the presence of high levels of impurities and other nucleic acids.

During PCR, impurities of high concentrations of either nucleic acids or proteins may significantly reduce the detection sensitivity. It is possible to detect one copy of a target sequence in the presence of 6.6 µg of genomic DNA, which is equivalent to a DNA content of \(10^8\) mammalian cells in a reaction volume of 100 µL (Z. Long, unpublished data). When the reaction volume is reduced to 50 µL for the same PCR assay, the sensitivity is no longer one copy. The sensitivity can be restored to one copy when the nonspecific DNA level is reduced to 3.3 µg in a 50-µL reaction volume. Similar inhibitory effects on PCR have been observed in the presence of high concentrations of RNA, even when the target is DNA.

### 4 Statistical Assessment of Limit of Detection: Properties of Single

#### 4.1 Limit of Detection

The LOD is the lowest concentration of an analyte detectable in a sample by a well-defined assay with an acceptable detection confidence. Note that the level of analyte is not necessarily quantitated. Different assay systems may have very different LODs, and these have been described above. The LOD of a detection system is usually equal to the sensitivity of the system, except when the target copy numbers are low. For example, when the target copy number is one per sample and the detection sensitivity is one copy, the LOD may not equal one copy if only one replicate of the sample is tested because the detection confidence is only 63%. A confidence of less than 95% is usually unacceptable for statistical reasons. However, one can design a test strategy to analyze multiple replicates of a sample to achieve a one-copy LOD.

#### 4.2 Theoretical Limit

Any detection method has a limit. It is important to understand whether the limit is caused by the instrumentation/methodology or by something more fundamental such as the probability laws. When an assay has demonstrated a sensitivity of one copy in an appropriate assay validation, the LOD has reached the theoretical limit. At the theoretical limit, detecting or not detecting the target is no longer a definite event, but an issue of probability or likelihood.

According to the Poisson probability distribution, if samples taken from a homogeneous solution have a concentration of one target molecule per sample volume, 36.79% of the samples will contain no target at all, and 63.21% will contain one or more targets (Table 1). Of the 63.21% positive samples, a good proportion of samples will contain two or more targets instead of one. As the target concentration increases, the chance of obtaining a positive sample also increases. To be almost certain that each sample will contain at least one target, the concentration has to be greater than nine targets per sample.

Theoretically, one can detect one target in a sample obtained from a solution that has a concentration of less than one target per sample because there is a chance that a sample may contain one target. However, one
cannot detect less than one target in a given sample. In a given sample, the number of targets follows a discrete distribution of whole number with a minimum of zero, but the concentrations of target in solutions are continuous. It is important to understand such a difference.

4.3 Properties of Single

The sensitivity of a detection system has reached its maximum when the assay has demonstrated its ability to detect one copy of DNA. To prove such a sensitivity, one needs to perform a series of tests using a number of replicate samples obtained from a homogeneous solution containing one copy of target DNA per sample volume. It may also be done with a two- or three-copy concentration. However, a higher copy concentration requires a larger number of replicate samples. The results from the tests can be analyzed by a Yates-corrected chi-square test, as described previously.\(^{12}\) It is preferred that both the number of positive results and the number of negative results are \(\geq 5\) in performing the statistical test, in order to avoid misrepresentation of data. Theoretically, a higher target concentration corresponds to a smaller chance of obtaining a negative result. To reduce the sample size required to generate \(\geq 5\) negative and also \(\geq 5\) positive results, it is important to choose a concentration that has a similar probability of producing a balanced number of positive and negative results.

Although there is little that one can do to improve the sensitivity of a detection system once it has been optimized to detect one copy of DNA target in the appropriate test matrix, there is a lot one can do in designing the appropriate testing strategy to improve the probability of detection. The detection confidence of an assay is the probability of detecting a positive sample in one or more tests. At a concentration of one copy of target DNA per unit sample volume, the detection confidence can be increased to 95% by running three replicates of the test per sample. It can be further improved to a 98% detection confidence by using four replicates of the test (Figure 2a).

The relationships between the detection confidence and the number of replicates per test sample when the target concentrations are two and three copies per unit sample volume, are illustrated in Figure 2(b) and 2(c), respectively. For example, a 98% detection confidence can be obtained with only two replicates when the target concentration is two copies per unit sample volume. Up to 99.99% detection confidence is attainable with three replicates when the target concentration is three copies per unit sample volume. The probabilities of

</table>
where \( P \) is the probability of detection and \( x \) is the number of targets per sample (concentration). It is not difficult to find that there is a good chance of obtaining a positive sample even if the concentration is below one copy. Conversely, as shown in Table 1, if one can only afford to run one replicate per test sample and want to have a 99.99% confidence of detection, one can choose to lower the claimed LOD of the assay to 9–10 copies. It is important to realize that this can only be done when the detection system has already demonstrated a one-copy sensitivity. It is the claimed LOD that is reduced, not the sensitivity.

4.4 Beyond the Limit

Is it possible to go below one copy of detection? Is there a limit to detection at all, knowing that everything is probable? For low levels of target concentration (less than one copy per sample), according to the Poisson probability distribution [Equation 1]:

\[
P = 1 - e^{-x}
\]

where \( P \) is the probability of detection and \( x \) is the number of targets per sample (concentration). It is not difficult to find that there is a good chance of obtaining a positive sample even if the concentration is below one copy. For example, when \( x = 0.1 \), the probability of obtaining a positive sample is 9.5%. This is not a bad chance. However, to ensure a 99.0% detection confidence when \( x = 0.1 \), one must test at least 46 replicates of each sample (let the sample size be \( N \), then \((e^{-0.1})^N = 1 - 0.99\); solve the equation to obtain \( N \approx 46 \).

Hence the answer to the second question is that the resources are the limit to achieving less than one-copy sensitivity. Because of the cost and availability of materials, it is not practical to go beyond one-copy detection sensitivity. As discussed in section 3.4, it is possible to detect low levels (one copy or less) of DNA, but it is not possible to perform quantitation at similar levels. Hence detection can go beyond the limit but quantitation can not.

5 THE PROS AND CONS OF DNA AMPLIFICATION

The major advantage of DNA amplification is its unsurpassed sensitivity. Better than finding a needle in a haystack, PCR has proved to be extremely sensitive and reliable, once optimized and validated. However, because of its great sensitivity, there is a misconception among beginners that the sensitivity is the cause of false-positive results. PCR has been known to have a high propensity to generate false-positive results. There are many publications on how to control the problem of PCR contamination.\(^{18–25}\) Opposition to using PCR in critical areas such as diagnostic/forensic studies and quality control testing argues that PCR is inherited with contamination, so that applications of PCR are bound with faults. Some users even set 30 cycles as the maximum number of PCR cycles in order to avoid contamination. However, one should realize that it is neither the number of PCR cycles nor the sensitivity itself that causes false positives, but the laboratory environment, sample cross-contamination, contaminated equipment, reagents or poor techniques of the operator. It requires a minimum number of cycles (>30) and optimization to achieve one-copy sensitivity.\(^{12,13}\) Such sensitivity can be obtained without contamination if proper procedures are implemented and strictly followed by the operator.

To control false-positive results, it is necessary to implement physical barriers, proper air pressure and separate air handlers between the areas for clean reagents and source DNA materials and between pre-PCR and postamplification processes. Clean protective clothing including face-masks, and hair and shoe covers is highly recommended. Setting up proper sentinel and PCR reagent controls is essential to demonstrate contamination-free reagents and laboratory environment. Because both amplification and detection processes are contained within a closed system in the PE 7700 instrument, it minimizes the potential for product carryover contamination. The use of uracil N-glycosylase (UNG) prior to PCR further reduces false positives by digesting previously amplified DNA products that contain uracil instead of thymine and are therefore subjected to UNG digestion.

Accurate results are critical for diagnostics, forensics and quality control testing of biological samples. This applies to any detection system. A false-negative result could result in transmitting an infectious virus to patients who used a failed product. A false-positive result could mean a suspension of clinical trials or a halt in manufacture of a product. All these are very costly to the sponsor. The principle of the statistical considerations and the PCR assay optimization strategy described here can save these troubles. A properly optimized and executed PCR test can provide very high sensitivity, comparable to and sometimes even better than the time-consuming infectivity culture assays. The distinct characteristics of single target detection are not limited to PCR and may
NUCLEIC ACIDS STRUCTURE AND MAPPING

be applied to other detection systems that require single- 
copy sensitivity.

Hybridization of nucleic acid probes has been a key technique used in the exploration of the molecular biology of the cell. Use of this technique is now expanding into the field of clinical diagnostics for the detection of pathogens and genetic disorders. In a hybridization assay, a labeled nucleic acid probe of a particular sequence is used to detect the presence of a target nucleic acid sequence. The fundamental principals that guide the design of the nucleic acids hybridization probes and assays are reviewed in this article. New improvements that simplify the implementation of these assays and enhance their sensitivity are discussed. Coupling of hybridization with amplification of nucleic acids in vitro, which results in extremely sensitive detection of specific nucleic acids, are also described.

1 INTRODUCTION

Imagine that you have a magic reagent to which you add a droplet of a body fluid from a patient; you wait for a moment and a glow appears in the tube holding the mixture; the glow not only tells you which pathogen is responsible for the patient’s illness, but also indicates which drugs to use to treat the disease. Also imagine that you can perform this diagnosis before any symptoms of the disease appear, improving the chances of success with the treatment, and you can perform this test on a large population with ease. The creation and development of such reagents are the promise of nucleic acid-based detection and are the aspiration of a diverse community of researchers. At the heart of nucleic acid-based detection is the process of hybridization, in which a strand of nucleic acid anneals to its complement. A nucleic acid probe can identify its complement in a sea of unrelated molecules. The bonds that form between complementary strands are among the strongest macromolecular associations known. This combination of high specificity and strong bonds gives the nucleic acid probes their advantage over conventional probes that are often based on antibody–antigen interactions.

When a macromolecular probe such as an antibody binds to its target, the forces that hold them together are electrostatic attractions, hydrogen bonds, salt bridges and hydrophobic interactions, and the bonds are located in a complex three-dimensional pattern. When one needs a protein with the ability to recognize a given target molecule, it is not possible to design it from its primary amino acid sequences, because the rules that predict the shape of a protein from its sequence are not well understood. Even after the rules of protein folding have become clear, this task will remain extremely complex. However, the diversity of the antibody repertoire within mammalian circulatory systems has allowed us to circumvent this hindrance by selecting antibodies that are specific for purified targets. On the other hand, the interaction between a nucleic acid probe and its complement is distinguished from the interaction between an antibody and an antigen by the number and organization of the contacts between the two molecules. A nucleic acid probe forms an ordered series of hydrogen bonds between the complementary nucleotides of the probe and the target strands, and the placement of the bonds is determined by the order of the nucleotides. The hydrogen bonds are placed in a fixed three-dimensional context by stacking interactions that occur between neighboring bases in each strand. These features permit the design of a nucleic acid probe for any given target nucleic acid by simply selecting a complementary sequence. Moreover, the strength and the specificity of the designed probes can be predicted with high precision.\(^1\)

The technique of nucleic acids hybridization was first developed in the laboratory of Sol Speigelman.\(^{2–4}\) A brief history of the key developments in hybridization technology has been described by Keller and Manak.\(^5\)
The most familiar format for performing hybridization reactions has been to label the probes with radioactive atoms, fluorophores, or reporter enzymes, incubate them with denatured and immobilized DNA, remove the excess probes by extensive washing, and then detect the signal that is associated with the surface on which the target is immobilized. The amount of target can be quantitatively inferred from the strength of the signal. One of the most significant developments occurred after the discovery of restriction endonucleases and molecular cloning, which made it possible also to obtain information on the size of the DNA that contains the target of the probe.\(^{6,7}\) In these assays, a DNA sample is incubated with restriction enzymes, the variously sized fragments that are generated are fractionated within a gel by electrophoresis and then blotted on a nitrocellulose membrane, and labeled probes are hybridized to the fragments on the membrane.\(^{8}\) The analytical power of Southern blotting has made it a mainstay of molecular biology research. The power of this approach has been enhanced by the capability of generating single-stranded probes of defined sequence and high density labeling by in vitro transcription.\(^{9}\)

The technique of hybridization has been utilized to explore the flow of information within cells and has been instrumental in the discovery of a number of biological phenomena. For example, the very first hybridization experiment\(^{2}\) demonstrated that messenger RNAs are complementary to their DNA templates. The discovery that a large fraction of mammalian DNA contains small sequences that are repeated hundreds of times was accomplished in a very simple experiment in which the kinetics of reassociation of denatured calf thymus DNA were measured.\(^{10}\) Intragenic noncoding sequences (introns) were discovered in eukaryotic genes by hybridizing mRNAs to genomic DNA and then observing in electron micrographs that regions of the genomic DNA looped out from the heteroduplex because they did not have complementary sequences in the RNA.\(^{11}\) Hybridization reactions also have often been used to isolate homologous genes from other species. For example, from the knowledge that the engrailed gene in fruit flies is responsible for segmentation, it is possible to construct probes that can be used to isolate the homologous gene from humans, and to understand the role that it plays in human embryogenesis.\(^{12}\)

Recent developments in hybridization technology allow it to be used for the detection of pathogens, mutations, and molecular rearrangements in clinical diagnostic settings and for forensic analysis. It is now possible to determine the extent to which a human tissue is infected with a pathogen by probing for the nucleic acids of that pathogen. This mode of pathogen detection is different from conventional immunoassays where the immune response of the body to the pathogen is detected. For this reason, it is possible to detect pathogens in absence of, or before the onset of, the immune response. Any pathogen can be detected from the knowledge of its nucleic acid sequence. Similarly, mutations that are related to disease state can be detected by simple and automated procedures.

## 2 HYBRIDIZATION FORMATS

The physical properties of nucleic acids that exhibit measurable changes upon hybridization are viscosity, absorption of ultraviolet light, and circular dichroism. The magnitudes of these changes are so small that millimolar concentrations of nucleic acid are required to observe the changes. Therefore, in order to measure the degree of hybridization for targets that are present in smaller concentration range in a sample, it is necessary to label the probes with a label that can be detected with higher sensitivity. These labeled probes are incubated with the sample, the hybrids are immobilized on a solid surface, and the excess of the probes is removed by washing the surface. Finally, the quantity of the label that remains after the washing is determined. Since these assays utilize both liquid and solid phases, their format is referred to as heterogeneous. Recently, it has become possible to detect hybridization in a liquid phase without having to immobilize and isolate the hybrids. These assays are called homogeneous assays.

## 3 HETEROGENEOUS HYBRIDIZATION ASSAYS

In order to isolate probe–target hybrids, a number of different solid surfaces and immobilization formats have been explored. Among the solid surfaces that are utilized are filter papers, nitrocellulose and nylon membranes, plastic beads, the walls of test tubes, and paramagnetic particles. Each surface offers unique advantages. Nitrocellulose binds to denatured DNA by adsorption, and slows down its renaturation, but at the same time permits hybridization with probes that are in excess. Nylon membranes are mechanically stronger than nitrocellulose membranes and do not become brittle when subjected to heating and drying steps, and they can therefore be probed multiple times. Magnetic beads are microscopic ferromagnetic particles that are coated with silanes and coupled with specific oligonucleotides or with other affinity agents such as streptavidin. Hybrids attached to the paramagnetic particles via the affinity agents and then can be isolated with a permanent magnet which causes the particles to stick to the wall.
of the test tube and the supernatant can be withdrawn by aspiration. Another advantage of paramagnetic particles is their large surface area, which provides a high binding capacity. Sometimes the surface of plastic dipsticks, test tubes or microtiter wells is used to immobilize hybrids. Although this markedly simplifies the assays, this mode of hybrid immobilization suffers from poor binding capacity. Glass surfaces, such as microscope slides, are commonly used when the probes have a fluorescent label.

There are a number of different immobilization formats for isolating probe–target hybrids from the excess of labeled probes. The most common method is to immobilize the denatured target nucleic acid and to perform the hybridization by immersing the solid medium in a solution of labeled probes. This is followed by washing the surface under conditions that maintain the hybrids but remove the excess probes. A second method is to immobilize a series of different probes at predetermined locations on a surface and then add labeled targets. In these assays, the location of the signal on the surface identifies the targets that are present in the sample. The third method is to perform the hybridization in solution and then immobilize the hybrids on surfaces. A fourth method is to perform assays in which the target is sandwiched between two probes, one of which serves as a label probe and the other serves as a capture probe. In these assays, the presence of the signal indirectly indicates the presence of the target, since the target bridges the signal and the capture probes. Finally, fixed tissue sections can be used for in situ hybridization, where the target molecules are naturally immobilized within the cellular matrix and the probes are hybridized to the targets at their original location.

3.1 Target Immobilization

Southern blotting is the most traditional and commonly used hybridization format, named after the developer of the technique. This format is used in molecular cloning experiments to identify bacterial colonies that contain a particular nucleic acid target sequence. It is also used in the determination of the size of the RNA or DNA that contains a particular target sequence. The applications of this format range from the ‘fingerprinting’ of human DNA for forensics to the study of changes in the level of expression for particular RNAs upon treatment with drugs. In performing Southern hybridizations, the targets are denatured in situ, i.e. within the bacterial colony or within the gel that is used to segregate the nucleic acids by size, and then transferred to a nitrocellulose or nylon membrane. The DNA attached to the membrane is then hybridized to a radioactively labeled probe, excess probes are washed away, and autoradiography is performed to locate the position of colonies or bands.

The power of this method is illustrated by an example in which different Mycobacterium tuberculosis isolates are typed in order to track the transmission of the disease in human populations. In this method, Mycobacterium tuberculosis is cultured from infected patients and its genomic DNA is isolated. The DNA is incubated with the restriction enzyme Pvu II, which cleaves it at a number of specific locations, generating a number of fragments of different lengths. Digested DNA from Mycobacterium tuberculosis bacteria that are isolated from different individuals are electrophoresed in different lanes of an agarose slab gel, in which different fragments are separated according to their size. The fractionated DNAs are transferred to a nylon membrane and hybridized to a 325-nucleotide long radioactively labeled probe that is specific for the insertion sequence IS6110. This insertion element, which is present at multiple sites, has a tendency to hop randomly from one place to another in the genome of Mycobacterium tuberculosis. Owing to this tendency of the insertion sequence, different sets of fragments are labeled by the probe for different strains of the bacterium. Thus, each strain produces a characteristic pattern of bands in the autoradiogram (Figure 1). Using this ‘fingerprint’, it is possible to identify each isolate and to chart the spread of a strain as it is transmitted within a population.

![Figure 1](image_url)

3.2 Probe Immobilization

The second most common mode of isolation of probe–target hybrids is via immobilized probes. In this format the probes are linked to unique positions on a solid surface and the target is labeled. This format permits the interrogation of a sample for the presence of multiple sequences, as a number of different probes can be linked to different locations on the solid surface. The location of the signals indicate which sequences are present in the sample. With the advances in the chemistry of DNA synthesis and immobilization, it has become possible to attach thousands of different probes in an area as small as 1 cm² and inquire whether a target contains their complement. These high-density arrays of immobilized probes are commonly known as ‘DNA chips’.

3.3 Hybrid Immobilization

Specific immobilization of probe–target hybrids is uncommon because of the lack of physical methods that can distinguish probe–target duplexes from unrelated double-stranded DNA. However, in the case of RNA–DNA hybrids, it has been possible to raise an antibody that recognizes RNA–DNA heteroduplexes. This antibody is used to immobilize the hybrids on solid surfaces. In these assays, the antibody that recognizes the RNA–DNA hybrid is attached to the surface of microtiter wells, the hybridization mixture is added to the well, and excess probes are washed away (Figure 2). The RNA probes are constructed in such a way that each probe carries many biotin moieties. A second antibody (or, in some cases, streptavidin) that binds to the biotin moieties in the probes and is also attached to a reporter is added to develop the signals.

3.4 Sandwich Hybridization

When hybridization is performed on solid surfaces with immobilized target or probes, the hybridization proceeds slowly and does not attain its full potential because the access to the targets or the probes is hindered. In addition, the surfaces bind nonspecifically to labeled probes and thereby obscure the weak signals emanating from rare targets. One of the schemes that make the signals more dependent on the presence of the targets is sandwich hybridization, in which two probes are utilized simultaneously. The first probe serves as a capture probe, and can bind both to the solid surface and to the target. The second probe is a reporter probe, which can bind to the target at a second site and carries a reporter group. Thus, the association of the signal to the solid surface is strictly target dependent (Figure 3).

Usually, in sandwich hybridization assays the hybridizations are performed in solution and the hybrids are then transferred to a solid surface. Among the means for immobilization of the capture probes are biotin–streptavidin links or oligo-dT : oligo-dA links. Sandwich hybridization reactions often decrease background signals to undetectable levels. However, when the detection is made highly sensitive, low-level background signals become significant. In order to reduce background signals further, a number of modifications in the basic sandwich hybridization format have been used. For example, in a reversible target capture scheme hybrids are eluted from paramagnetic particles after removal of the excess probes and recaptured on to the surface of a new set of paramagnetic particles. Nonspecifically bound probes which contribute to the background are discarded along with the first set of particles. The capture and release steps are repeated several times to attain extremely sensitive detection.
3.5 In Situ Hybridization

In situ hybridization is utilized to determine the location of specific nucleic acid sequences within tissues. It can also be used to detect specific sequences in particular subcellular domains, such as the cytoplasm, the nucleolus or the chromosomes. In situ hybridization reactions in entire organisms, such as insects or rodent embryos, are also possible. During in situ hybridization, the nucleic acid targets remain trapped within the cellular matrix, while remaining accessible to probes. In order to make the nucleic acids targets accessible to probes, while maintaining the cellular and histological integrity of the specimens, they are ‘fixed’ with reagents that remove membranes and cross-link proteins. Fixed specimens can withstand the rigors of hybridization, washing, and signal development.

The probes for in situ hybridization are radioactively labeled or labeled with tags that can generate color or fluorescence at the site of hybridization. In order to confine the signal to the hybridization site in intracellular localization experiments, $^{35}$S-labeled probes and emulsion autoradiography are often utilized. The radiation from the $^{35}$S radionuclide can travel only short distances and the photosensitive emulsion is in intimate contact with the specimen ensuring high-resolution images. High-resolution images of the target distribution can also be obtained by utilizing fluorescence labels in thin tissue sections.

In the following example, in situ hybridization is used to map the distribution of two particular mRNAs within embryos of the fruit fly, Drosophila melanogaster. The target nucleic acids were bicoid and oskar mRNAs that localize at the anterior and the posterior ends of early preblastoderm embryos. RNA probes that are complementary to each of these mRNAs are prepared by in vitro transcription of the cloned genes encoding these RNAs. Digoxygenin-bearing nucleotides are incorporated into these probes during in vitro transcription. After permeabilization and fixing, the embryos are incubated with the probes. Excess probes are removed by several rounds of washing. The signal is developed in a series of reactions in which the embryos are first incubated with an antibody that is conjugated to alkaline phosphatase that can bind to the digoxygenin moiety. Further washing removes the antibody–alkaline phosphatase conjugates that are not bound to digoxygenin moieties and then a chromogenic substrate of the alkaline phosphatase, nitroblue tetrazolium, is added. A bluish-purple precipitate is created by the alkaline phosphatase wherever the RNA is localized. The gradient of color stemming from the two poles of the embryo indicated the distribution of the two RNA molecules (Figure 4).

**Figure 4** Detection of localized mRNAs in an early embryo of Drosophila melanogaster by in situ hybridization. The bicoid mRNA localizes at the anterior end and the oskar mRNA localizes at the posterior end of the embryo. (Courtesy of P. Tolias.)

4 LABELS

A number of different labeling schemes, including the use of radioactive atoms, fluorescent moieties, chemiluminescence generating systems, and enzymatic reporters, have been explored in the construction of DNA probes, some of them having been inherited from immunoassays. Radioactive $^{32}$P is a natural label for nucleic acids since it can be incorporated into their backbone during synthesis with radioactive nucleoside triphosphates. In order to improve the resolution of the autoradiograms, $^{35}$S is used since the radiation from $^{35}$S can only travel short distances. $^{35}$S can also be introduced into the probes via radioactive nucleotide triphosphates. For reasons of safety, stability, and waste disposal, nonradioactive labels have been utilized. Among the nonradioactive labels that can provide sensitivity equivalent to radioactive labels are enzymatic labels that turn a colorless substrate into a colored product or turn a nonfluorescent substrate into a fluorescent product. Enzymatic labels can produce several thousand detectable products due to catalytic turnover. Commonly used enzymatic labels are alkaline phosphatase, horseradish peroxidase, and β-galactosidase. Most often, enzymatic labels are introduced indirectly in the assay schemes because hybridization conditions denature proteins, and the bulk of the proteins may interfere with hybridization. A common mechanism of indirect labeling is to incorporate a small hapten such as a biotin moiety during the synthesis of the hybridization probe, add an enzyme-linked antibody for the hapten, and then remove the excess antibodies. Signals are developed by adding the substrate for the enzyme. In addition to chromogenic substrates, chemicals that can participate in a light-generating reaction are also commonly employed. These chemiluminescent labels provide very high sensitivity and can be used just like radioactive labels because both autoradiography and scintillation counting can be performed to
Recently, fluorophores have become common labeling moieties. Fluorescent labeling moieties do not offer a sensitivity as high as radioactivity and enzymatic labels, but they have become popular because rare targets can be made to be more abundant by nucleic acid amplification. Another reason for using fluorescent labels is that high sensitivity can be achieved when localized signals are viewed under the microscope.

5 HOMOGENEOUS HYBRIDIZATION ASSAYS

Although hybridization assays that rely on the isolation of probe–target hybrids offer high sensitivity, they are cumbersome to perform. In addition, the requirement for immobilization and washing precludes their use in the real-time monitoring of processes that produce nucleic acids. It is necessary to sample the reactions at different times and quantify the products at a later time. In addition, in order to detect nucleic acids within cells, the cells have to be fixed to permit removal of the probes. It is desirable to follow the progress of nucleic acid synthesis reactions without interruption and to detect nucleic acids in living cells and organisms without killing them. Several assays have recently been developed that can detect nucleic acids in homogeneous solutions without the need to isolate the probe–target hybrids. These assays utilize interactive fluorescence reporters that exchange energy in a distance-dependent manner.

The earliest homogeneous hybridization assays based on fluorescence resonance energy transfer (FRET) utilized two oligonucleotides that bind to neighboring sites on a target. One probe in this binary probe system carries a donor fluorescent moiety at its 3' end, and the other probe carries an acceptor fluorescent moiety at its 5' end. The donor and acceptor fluorophores are chosen so that efficient energy transfer can take place from the donor to the acceptor when the two probes are in close proximity, whereas no energy transfer should occur when the two probes are apart from each other and are free in solution. Energy transfer, which is measured by the decrease in donor fluorescence or the increase in acceptor fluorescence, indicates the extent of hybridization and can be used to follow hybridization in real time (Figure 5a). An additional benefit of this approach is higher specificity, as two probes, rather than one, must bind to the target in order to generate a signal.

A second approach that uses FRET in homogeneous hybridization assays also uses a pair of oligonucleotides, one of which is designed to be complementary both to the target strand and to the other oligonucleotide. The 5' end of one oligonucleotide is labeled with a donor fluorophore and the 3' end of the other oligonucleotide is labeled with an acceptor fluorophore, such that when the two oligonucleotides anneal to each other the two labels are next to each other and exhibit efficient energy transfer. Since the binding of two small oligonucleotides is a dynamic process, when the target is added some of the oligonucleotides bind to the target, resulting in a decrease in energy transfer (Figure 5b). Thus, the extent of increase in the fluorescence of the donor fluorophore and the extent of decrease in the fluorescence of the acceptor fluorophore indicate the extent of hybridization.

In a third approach, the donor and acceptor fluorophores are attached at two ends of the same
oligonucleotide, which serves as the probe. Since an oligonucleotide in solution behaves like a random coil, the two ends sometimes come close enough to each other within the lifetime of the excited state of the donor fluorophore that some energy transfer occurs. However, when the probe binds to its target, the two ends are permanently kept away from each other, precluding energy transfer (Figure 5c). Although, the magnitude of the changes in energy transfer is relatively modest, it is possible to use it for monitoring hybridization.\(^{(31)}\)

Another limitation of doubly labeled random-coil probes, in addition to the relatively small changes in fluorescence that occur upon hybridization, is that the magnitude of the changes decrease with the length of the probe. A fourth approach based on energy transfer solves these problems by introducing small complementary sequences on either end of the probe that brings the two labels in close proximity through the formation of a hairpin stem. The length of the stem sequences is chosen such that the formation of a probe–target hybrid readily disrupts the stem and removes the fluorophore from the vicinity of the quencher (Figure 5d). These probes, called molecular beacons, have an additional useful feature: the acceptor moiety is a nonfluorescent quencher dye.\(^{(32,33)}\) As a consequence, nonhybridized molecular beacons are dark and hybridized ones are fluorescent (Figure 6). In addition, the hairpin stems of these probes bring the fluorophore and the quencher so close to each other that energy transfer takes place by more efficient mechanisms than FRET, resulting in a very high level of quenching. Furthermore, these close-distance energy transfer mechanisms do not require any particular relationship between the spectra of the fluorophore and the quencher, as FRET-based mechanisms do. As a consequence, well-quenched probes can be constructed from any fluorophore, allowing multiplex assays for many different targets in the same solution.

### 6 TARGET AMPLIFICATION

One of the reasons why hybridization-based assays did not find widespread utility in clinical laboratories for a long time is that targets that are clinically relevant are often rare constituents of biological samples. For example, pathogens, such as the human immunodeficiency virus, may be present in as few as one in \(10^6\) human cells, yet that individual may still be infectious. Another significant factor is the complexity of these assays. These limitations have been overcome by the development of techniques for the selective in vitro amplification of target nucleic acids. The most developed of these techniques is the polymerase chain reaction (PCR).\(^{(34)}\) In this process, a specific nucleic acid sequence is amplified using two oligonucleotide primers, deoxyribonucleotides, a thermostable DNA polymerase, and a thermal cycler. The primers hybridize to opposite strands of the target sequence and initiate product strand synthesis by DNA polymerase and the thermal cycler denatures the double-stranded templates by raising the temperature. As the temperature of the reaction mixture is cycled between the stages of denaturation and annealing, the number of the DNA fragments defined by the two primers doubles every cycle. As a result of this exponential amplification, the target sequence is enriched more than \(10^6\)-fold. After selective enrichment, the target sequences can readily be detected by hybridization.

In addition to the PCR, there are two other well-developed target amplification schemes: strand displacement amplification\(^{(35)}\) and transcription-based amplification.\(^{(36)}\) These techniques also utilize a pair of specific primers to amplify a region of the target. These methods accomplish the denaturation of double-stranded products by enzymatic means rather than via thermal denaturation, and the amplification can therefore be performed at one uniform temperature, eliminating the need for a thermal cycling device. Strand displacement amplification utilizes a DNA polymerase that displaces the DNA strand complementary to the template strand while extending the primer. The extendable 3’ ends are created by the nicking activity of a restriction endonuclease. The displaced strands serve as templates for further rounds of synthesis. As a result, the DNA is amplified exponentially as long as the primers and the enzymes remain in excess.\(^{(35)}\)

![Figure 6](image-url)  
*Figure 6* Detecting a specific nucleic acid in homogeneous solution with a molecular beacon. Two test tubes that contain a solution of the molecular beacon probe are illuminated with an ultraviolet lamp. The tube on the left also contains a target for the molecular beacon.
Transcription-based amplification utilizes the RNA polymerase of bacteriophage T7, reverse transcriptase, and ribonuclease H in a concerted reaction. The initial RNA templates are copied by reverse transcription and one of the primers carries a tail corresponding to the bottom strand of the T7 RNA polymerase promoter. The original RNA in the resulting RNA–DNA hybrid is degraded by the action of ribonuclease H. The second primer then binds to the single-stranded DNA and is extended by the natural DNA polymerase activity of the reverse transcriptase, creating a functional promoter for the T7 RNA polymerase. The T7 RNA polymerase then generate more than 100 copies of the DNA template. Owing to the high turnover rate of T7 RNA polymerase, this reaction also produces large-scale amplification of the target.\(^{36}\)

In order to result in amplification, both primers must bind to their targets in each cycle of PCR, and sometimes, especially with nucleic acids of high complexity, nonspecific products are also amplified. As a result, it is necessary to analyze the products of amplification by electrophoresis, followed by a hybridization step to identify the desired amplification product. In these confirmatory hybridization reactions, it is not necessary to use highly sensitive labels such as radioactive atoms or chromogenic enzymes. However, the assays remain labor intensive because of post-amplification analyses. In addition, the amplified DNA contaminates the laboratory and can become a source of false signals in future assays. Recently, the development of new homogeneous hybridization techniques has solved these problems by linking specific hybridization with nucleic acid amplification. It is now possible to perform extremely sensitive detection of specific sequences in a sealed assay tube.

The homogeneous hybridization techniques discussed above can be used to detect the product of amplification in the same tube in which the reaction is carried out. In addition, it is possible to monitor the progress of these reactions in real time, which enables quantitation of the initial template within an extremely wide dynamic range.\(^{32,37,38}\) Although each of the target amplification schemes mentioned above can be monitored with a homogeneous hybridization method, we shall discuss the use of molecular beacons as an example of real-time monitoring of amplification reactions.

In order to monitor the progress of a PCR, a molecular beacon whose loop sequence is designed to be complementary to a region of the expected amplification product is included in the reaction mixture. The length of the arm sequences of molecular beacons is chosen so that the stem is stable at the annealing temperature of the PCR. The length of the loop sequence is chosen so that the probe–target hybrid would be stable at the annealing temperature also. During the denaturation step of the PCR, the molecular beacons assume a random coil configuration and fluoresce. As the temperature is lowered to allow annealing of the primers, stem hybrids form rapidly, preventing fluorescence. However, at the annealing temperature, the molecular beacons bind to the complementary strand in the amplified DNA and generate fluorescence. When the temperature is raised to allow primer extension, the molecular beacons dissociate from their targets and do not interfere with polymerization. A new round of hybridization takes place in the annealing step of every cycle, and the intensity of the resulting fluorescence indicates the amount of accumulated amplified DNA (Figure 7a). The number of thermal cycles that it takes for the fluorescence intensity to reach a detectable value is inversely proportional to the

![Figure 7](attachment:image.png)

**Figure 7** Real-time measurement of amplicon synthesis during PCR using molecular beacons. (a) Change in fluorescence in seven reactions, each initiated with a different number of template molecules (indicated), is plotted against the number of cycles. (b) The threshold cycle, the cycle at which the signal becomes detectable, is plotted against the logarithm of the initial number of templates.
logarithm of the number of template molecules that are initially present in a reaction (Figure 7b). These extremely sensitive and quantitative assays can be performed in a single tube and require one operational step in which the reaction mixture is assembled.

In addition to molecular beacon probes, other homogeneous methods of hybridization can also be used to monitor the progress of amplification reactions. FRET-based binary probes can be used to perform real-time PCR. The two probes that bind to adjacent sites on the DNA strand being amplified are added in the initial reaction mixture along with the primers. In order to monitor the progress of the reaction in real time, the extent of resonance energy transfer is measured continuously during the reaction. Similarly, random-coil probes labeled with two interacting fluorophores can also be used to monitor the progress of PCRs in real time. These probes can draw additional benefit from the natural endonucleolytic activity of DNA polymerase, since this activity results in cleavage of the probe that the polymerase finds sitting in its tract during polymerization. Since the cleaved fragments diffuse away from each other are not able to participate in FRET, the fluorescence increases and provides a measure of the progress of the PCR. With reference to the 5'-3’ endonucleolytic activity of the Taq DNA polymerase, these probes are called TaqMan probes. Interfacing these homogeneous hybridization methods with amplification reactions allows the simple and sensitive detection of rare nucleic acids that are present in complex nucleic acid mixtures.

7 PROBE AMPLIFICATION

In vitro amplification of target sequences is highly effective for the detection of rare sequences. An alternative strategy is to amplify the signals associated with the probes themselves. For example, by using reporter enzymes it is possible to generate 1000 detectable signal moieties for every probe that is bound to its target. However, higher levels of amplifications are required for the detection of rare pathogens in clinical samples. There are three strategies that provide the required degree of amplification: RNA hybridization probes that can be amplified by Qβ-replicase, branched-DNA probes that form dendrimeric complexes, and padlock probes that can initiate rolling circle amplification. Assays based on these signal amplification techniques are as sensitive as those based on target amplification techniques.

The Qβ replicase-mediated amplification system relies upon bifunctional recombinant RNA probes that can serve as hybridization probes and can be amplified exponentially upon incubation with the RNA-directed RNA polymerase isolated from Escherichia coli infected with bacteriophage Qβ. This system exploits the ability of Qβ replicase to amplify naturally occurring RNA templates such as midivariant-1 (MDV-1) RNA. These RNAs have evolved to serve as templates for Qβ replicase. Their replication does not require primers and strand separation occurs naturally at 37°C owing to the self-structure of the RNA and to the action of the replicase. RNAs that replicate exponentially possess an internal replicase binding site, a particular 3’-terminal sequence for the initiation of replication, and a particular 5’-terminal sequence that encodes the 3’-terminal initiation sequence needed for the initiation of synthesis from the product strand. Hybridization probe sequences are inserted within a region of the MDV-1 RNA that preserves the elements that are necessary for replication. In order to perform assays that detect rare targets, these probes are hybridized to the target along with capture probes, the hybrids are collected on the surface of paramagnetic particles, excess of the probes is removed by washing, the hybrids are eluted into a solution, and finally Qβ replicase is added to the eluted hybrids, amplifying the probes 1011-fold in a 30-min incubation. The amplified RNA can be detected by fluorescence of an intercalating dye. In order to ensure that the nonspecifically bound probes that survived the stringent washing do not produce a signal, an additional target-dependent step has been interjected in these assays. This involves using recombinant RNA probes that are broken into two pieces in the middle of the probe region, neither of which can be amplified exponentially on its own. However, when the two segments of the probe are brought next to each other by binding to the target, they can be ligated together, generating fully functional replicating RNA (Figure 8). With binary hybridization probes that become replicatable by the mediation of the target, it is possible to detect as few as 100 copies of a target in a complex nucleic sample.

A second approach which relies on the hybridization probes to give a signal that is substantially larger than the number of probes is based on the use of branched DNA probes. These probes bind specifically to their target and carry multiple branches that stem from the hydroxyl functionalities of the deoxyribose sugars. These branches themselves are oligonucleotide sequences to which other branched DNA oligonucleotides can be attached. Depending upon the valency of each branched oligonucleotide and upon the number of successive layers that are used, a very large dendrimeric structure can be assembled. Reporter enzymes are attached at multiple locations on the branches of these dendrimers. Thus, each target sequence results in a large number of detectable labels after the signals are developed.
In a third approach, circularizing oligonucleotide probes (padlock probes) are utilized. The 5' and 3' end regions of these linear oligonucleotides are designed to base pair next to each other on a target strand. If properly hybridized, the two ends can be joined by target-dependent enzymatic ligation, converting the linear probes to circular molecules that are catenated to the target sequence. Owing to this topological linkage with the target, the hybrids can be washed with extremely high stringency, markedly enhancing the assay specificity. The probe remains associated with the target molecule even when the hybrid is disrupted. This permits localized detection of target sequences on a chromosome with fluorescence. In addition to permitting stringent washing, the circularized probes allow signal amplification by a rolling-circle replication mechanism. In this DNA synthesis process, a primer is annealed to the circle and extended with a DNA polymerase. DNA polymerase extends the primer using the circle as a template and when it reaches the tail of the primer, the polymerase begins to displace the primer and the extended product. Product strand displacement continues indefinitely, resulting in the synthesis of a very long DNA containing a tendemly repeated copy of the circularized probe. This multimeric linear copy of the probe can be exponentially copied by including a second primer that can bind to the product strand. When the second primer binds, a cascade of DNA synthesis and strand displacement ensues, resulting in the synthesis of a large amount of DNA. This serves as a signal indicating the presence of the target to which the circularizing probes were initially bound.

8 MUTATION DETECTION

Accelerated by the human genome project, a large number of genetic variations are being discovered, some of which are linked to genetic disorders. Therefore, the task of detecting specific sequences often involves distinguishing closely related sequences that can differ from each other by only a single nucleotide substitution. Although oligonucleotide probes are exquisitely specific, their power to discriminate between closely related targets decreases as their length increases. As the length of the probe is increased, the free energy penalty resulting from a mismatched base pair in a probe–target duplex represents a smaller and smaller fraction of the total free energy change associated with binding. Consequently, allele-specific oligonucleotides for a target region have to be found by making them progressively smaller and by making the conditions of hybridization progressively more stringent. Several groups have described ways of improving the specificity of oligonucleotide probes by making them more structured. This can be accomplished by embedding the oligonucleotides within hairpin stems or by circularizing them. Alternatively, specific enzymes that recognize matched or mismatched base pairs are recruited to enhance the level of discrimination.

In order to detect single-nucleotide variations in clinical diagnostic settings, or for the discovery of relationships between genotype and disease, it is important to be able to perform accurate assays on a large number of samples.
A number of techniques that have been conventionally used for the detection of mutations have been described by Cotton. There are two recent techniques that can accurately detect mutations and can be used in formats that have high throughput: one is based on the use of homogeneous hybridization probes coupled to PCR, and the second is a cleavage assay that utilizes the specificity of ‘flap’ endonuclease from *Pyrococcus furiosus*. The first technique employs real-time PCRs to amplify a region of the DNA that contains the single-nucleotide variation of interest in the presence of a pair of homogeneous hybridization probes. Either molecular beacons or Taq-Man probes can be employed in these assays. One of the probes is specific for one allele and is labeled with one color, whereas the second probe is specific to the other allele and is labeled with a different color. The color that develops indicates which allele is present. Since 96 reactions can be performed in parallel and the analysis is performed as the PCR proceeds, the throughput of these assays is so high that the genotypes of thousands of samples can be determined every week.

The cleavage assays utilize a flap endonuclease from *Pyrococcus furiosus* to cleave Y-shaped structures that are created by hybridizing two oligonucleotides to the region of the target at the site of the mutation (Figure 9). These Y-shaped structures are akin to those that arise naturally during DNA synthesis when the 3′ end of a growing chain displaces the sequence that is bound to the template. The sequence in the displaced strand and the newly synthesized strand are the same and undergo back-and-forth branch migration. A number of enzymes associated with DNA repair, including DNA polymerase and flap endonuclease from *Pyrococcus furiosus*, have the capacity to excise these redundant portions of displaced DNA by nicking the displaced strand where it meets the template strand. The artificial Y structures are created by binding an ‘invader oligonucleotide’ and a ‘signal oligonucleotide’ to the target at the same time (Figure 9). The 3′ end of the invader oligonucleotide share the same sequence with the 5′ end of the signal oligonucleotide, permitting branch migration to create a substrate of the flap endonuclease. Cleavage results in a detectable signal, as FRET between the terminal labels of the signal probes is disrupted. Y-structures possessing a mismatched base pair at the junction of the two arms can not be cleaved. Hence, by using two variants of the signal probe where each is specific for a different allele and has a different reporter fluorophore, it is possible to discriminate between two alleles. The system is highly specific, because the specificity of the flap endonuclease is added to the specificity of hybridization probes.

9 TAKING DNA PROBES INTO A PROTEIN WORLD

All of the hybridization assays described so far make use of the ability of nucleic acid strands to anneal specifically to their complements. A new kind of DNA probe is being developed that expands the utility of nucleic acids beyond their traditional role as hybridization probes. These oligonucleotide probes do not hybridize to a complementary nucleic acid, but rather they bind to a protein target. These oligonucleotide probes assume a conformation that allows them to fit within a pocket of their protein target. These oligonucleotides are created and used in the image of antibodies. From the vast field of possible shapes and structures inherent in a partially or fully randomized collection of oligonucleotides, it is possible to isolate an oligonucleotide that can bind to any target of interest. A library of all possible sequences is created on a DNA synthesizer and an in vitro selection scheme is used for the isolation of a desired molecule. Methods of in vitro evolution and selection which allow for the isolation of a particular sequence from hundreds of billions of other possibilities were first introduced in 1967. These methods have recently been invigorated by the use of PCRs. Using a scheme termed SELEX (systematic evolution of ligands by exponential enrichment), it has been possible to find nucleic acid ligands for a wide variety of molecules including proteins and organic dyes.

In this scheme, a library of oligonucleotides is panned for the molecules that exhibit an affinity for a desired target. Those that are capable of binding to the target are
NUCLEIC ACIDS STRUCTURE AND MAPPING

exponentially amplified. This process is repeated until a molecule of desired specificity and affinity is found. For example, SELEX has been used to find a DNA ligand for vascular endothelial growth factor, a protein involved in angiogenesis. Using this DNA ligand as a detector probe and an antibody as a capture probe, an assay has been developed for the detection of vascular endothelial growth factor. The DNA ligand was tagged with a fluorescein moiety in order to produce a chemiluminescent signal via an antifluorescein antibody and an alkaline phosphatase detection system. This assay exhibits a specificity equivalent to common immunoassays.

The advantage of using nucleic acid ligands for proteins, as opposed to antibodies, is that animals are not required for the development of the diagnostic reagent. It may be possible to find ligands for poorly immunogenic targets. Knowledge of the sequence of a nucleic acid ligand allows its accurate reproduction anywhere in the world since its production is not subjected to animal-to-animal variations. For applications and detection methods in which the bulk of the antibodies is a limitation, the small size of nucleic acid ligands offers an advantage. In the conventional nucleic acid-based diagnostics, one can easily identify probes that characterize a pathogenic species or strain by using the knowledge of the nucleotide sequence of relatively invariant regions of genomes. Similarly, finding the antibodies for conventional immunoassays is also simple, because all one needs is an antigen, a syringe, and an animal. Based on the diversity of ligands isolated by SELEX, developers of this technique predict that nucleic acid ligands will also prove to be as general and easy to find as conventional nucleic acid probes and antibodies.

10 FUTURE PROSPECTS

The technique of hybridization has played a key role in the exploration of the molecular biology of the cell. Improvements that simplify its implementation and enhance its sensitivity are taking it to the realm of clinical diagnostics, where it is important that the technique is simple to perform and is amenable for automation. These developments will make it possible to map the distribution of miRNAs in living cells by microscopy and study gene expression in an ensemble of living cells with fluorescence-activated cell sorters. We shall see innovative use of DNA–DNA hybridization in the development of new materials for the construction of nanostructures. In addition, we shall witness the solution of computational problems by the utilization of the manifest specificity of oligonucleotides.

DNA molecules with unusual structures can have significant consequences in many DNA metabolic processes. This article summarizes structural studies of DNA molecules containing bulged and mismatched bases and trinucleotide repeating DNAs. Extra base bulges and mismatches in double-stranded DNA can arise from replication errors or imperfect recombination. If these lesions escape the repair system, they would subsequently cause mutagenesis. Using a combination of gel electrophoresis, electron microscopy (EM), chemical modification, and probing with RecA protein, the structure of bulged and mismatched DNAs was examined and factors such as base composition and flanking base sequence have been shown to influence the overall structure of these molecules.

Expansion of trinucleotide repeats is a major cause of several inherited neurodegenerative diseases. Described here are findings that show, by in vitro nucleosome assembly assay, that the expanded CTG triplet sequences derived from myotonic dystrophy (DM) patients form the most stable naturally occurring nucleosomes that are known. In contrast, long tracts of repeating CCG triplets (expanded in fragile X syndrome (FraX) patients) resist nucleosome assembly. This information could provide critical clues about how these unusual DNAs cause harmful biological effects in living cells.

1 INTRODUCTION

DNA molecules can possess structural polymorphism depending on base composition, sequence arrangement, and many other factors. Various structures of DNA molecules could determine their fate in DNA metabolic processes. Our research interest is to understand the structure and function of unusual DNA sequences which could cause mutagenesis and diseases in living cells.

Extra base bulges and mismatches in double-stranded DNA can arise from recombination between sequences that are not fully homologous or from errors of replication. Bulged bases resulting from replicative errors are considered to play an important role in frame-shift mutagenesis. In Escherichia coli, mismatches can be repaired by the methyl-directed repair system and several short-patch mismatch repair pathways, and the repair efficiency depends on the type of mismatch and the sequence context. Genetic studies have shown that single-base bulges can also be repaired by the methyl-directed repair system in E. coli and, using cell extracts, this repair system has been shown to repair DNAs containing 1–3-base bulges as efficiently as a G-T mismatch.

Human homologs of mismatch repair proteins have been identified: hMSH2-6 are bacterial MutS homologs and hMLH1, hPMS1, and hPMS2 are homologs of bacterial MutL. Mutations of these genes have been shown to be responsible for almost all patients with hereditary nonpolyposis colorectal cancer, in which simple repetitive DNA sequences have a high incidence of mutation. Biochemical and genetic studies have demonstrated that these human repair proteins possess different affinities for DNA containing bulges and mismatches depending upon the type and number of bases. Therefore, it is critical to understand the structure of DNA containing bulges and mismatches and examine the determining factors such as base composition, flanking
sequences and number of bases. This article describes our studies using a variety of biochemical assays to investigate the structure and properties of short duplex DNA molecules containing bulged and mismatched bases.

Since 1991, 12 human genetic diseases including DM and FraX have been shown to be caused by expansion of trinucleotide repeats. In each disease, an expanded block of repeating trinucleotides is present in or near a gene whose loss or alteration leads to the disease. The repeating triplet blocks present in normal individuals at these loci are heterogeneous in size and have less than 35 copies. In the afflicted person there can be as many as 2000 repeats. The diseases have been divided into two groups based on the location of the expanded triplet within the disease gene. The first group includes DM, FraX and Friedreich’s ataxia, in which the triplet blocks are not in the protein coding regions. In these diseases, the triplet blocks must expand beyond ~100 repeats for the full disease symptoms to appear and perfect triplet runs are much more deleterious than longer blocks that contain scattered interruptions. In the second group, including Huntington’s and Kennedy’s diseases, the expanded triplet repeats are within the protein coding sequences. Thus, expansion by a smaller number of CAG/CTG repeats that encode polyglutamine tracts in the disease protein alter or abolish its activity. The triplet diseases frequently show unusual genetics (anticipation), in which the severity of the disease increases with succeeding generations. Disease symptoms also correlate with the size of the expanded triplet block.

For each triplet disease, two major questions need to be answered: what is the mechanism of expansion of triplet repeats? and how does the expanded triplet repeat in each disease lead to clinical symptoms? In this article, we summarize our studies, showing that repeating sequences CTG (in DM) and CCG (in FraX) have extremely unusual properties in forming nucleosomes. Thus, the biological manifestations of DM and FraX diseases are likely to be due in part to the unusual properties of DNAs containing very long triplet repeats and the resulting unusual chromatin structures.

2 STRUCTURE AND PROPERTIES OF DNA CONTAINING BULGES AND MISMATCHES

Structural studies using nuclear magnetic resonance (NMR) spectroscopy suggest that bulged bases can exist in either a stacked-in or looped-out conformation depending on the base composition of the bulge, temperature, and other factors. Gel electrophoretic studies in our laboratory (see below) and the laboratories of Lilley and Crothers have shown that bulges of 1–5-bases produce kinks in DNA, which result in decreased mobilities of bulged DNAs in polyacrylamide gels. Whereas single-base bulges produce kinks in DNA, studies using NMR, X-ray crystallography and gel electrophoresis show that single-base mismatches do not. Furthermore, DNA containing multiple base mismatches shows no retardation of gel mobility in 15% polyacrylamide gels. These results suggest that mismatched bases remain stacked into the helix and produce at most only subtle perturbations in the DNA helix.

We have applied a combination of gel electrophoresis, EM, chemical modification, and RecA probing techniques to understand further the structure and properties of short duplex DNA molecules containing either bulges or mismatches.

2.1 Gel Electrophoretic Analysis of DNAs Containing Base Bulges and Mismatches

Gel electrophoresis and EM have been used to examine the effects of 1–4 extra bases on the structure of DNA. DNA duplexes of 32 basepairs (bps) were synthesized containing unique single-stranded ends such that upon ligation the 32-mers can only join in a head-to-tail fashion. The 32-mers were synthesized to contain various arrangements of single or multiple extra bases. The effect of the extra bases on each 32-mer was amplified by the ligation process which places the extra bases in phase with the helix in the linear and circular multimers. It was observed that single extra bases caused a marked retardation of the electrophoretic mobility of the linear multimers, indicating that the bulged bases kinked the DNA. Analysis of the size distribution of the circular multimers confirmed this observation. DNAs with two to four extra bases at a single site showed even greater electrophoretic retardations and yielded smaller circular multimers. Placing the extra base(s) out of phase with the helix created kinks which canceled each other and produced no net retardation.

The effects of bulge composition and flanking sequence on the kinking of DNA by bulged bases were further investigated in this way. Synthetic 30 bp duplex DNAs containing two single-base bulges spaced by 10 bp were ligated head-to-tail, and their electrophoretic behavior in highly cross-linked gels was examined. All bulge-containing DNAs showed marked electrophoretic retardations compared with non-bulge-containing DNA. Regardless of the sequence of the flanking bps, purine bulges produced greater retardations than pyrimidine bulges. Furthermore, bulged C and Ts produced the same retardations as did bulged G and As. Bulged DNA containing different flanking bps showed marked differences
in electrophoretic mobility, for example, the G-C and C-G flanking bps were seen to have very different effects (Figure 1). Thus, these results imply an important role of base stacking in determining how neighboring bps influence the kinking of DNA by a single-base bulge. We have applied the same techniques to examine DNAs containing single-base mismatches. Twenty-four DNAs containing eight possible mismatches with three different flanking sequences (A-T, G-C, or a combination of the two) were analyzed on 15% polyacrylamide gels and showed no detectable retardation in electrophoretic mobility.

2.2 Visualization of Three-base Bulged DNAs by Electron Microscopy and Estimation of the Kinking Angle Produced by the Bulges

The demonstration that bulged bases produce electrophoretic retardations has provided a means of screening for small chromosomal deletions or insertions. For example, nearly 70% of the carriers of cystic fibrosis (CF) in the western Caucasian population possess a single three-base deletion (ΔF508) in the CF gene on chromosome 7. Several groups have used the polymerase chain reaction (PCR) to amplify small regions of DNA (100 bp) around codon 508 of the CF gene if the DNA is from a carrier of the disease and thus a heterozygote, amplification produces four single-stranded DNA fragments, two that contain the deletion and two that do not. Upon annealing the four DNA strands, two homoduplexes and two heteroduplexes (one containing a CTT bulge and the other containing an AAG bulge) are produced, and the latter species can be detected by their retarded electrophoretic mobility. This approach has also been used to screen for a four-base insertion mutation in Tay–Sachs disease.

For these genetic screens to be useful and to understand further the structure of bulge-containing DNA, it is important to measure directly the kinking angle produced in a DNA by a bulged base and to examine the distribution of kinking angles within the population of bulged DNAs. To approach this problem we obtained DNA from a CF carrier. The CF homoduplex and bulge-containing heteroduplex molecules were prepared as described above. These DNAs were examined by EM for the presence of visible kinks. Twice as many bulge-containing

a DNAs amplified by PCR from the DNA of a CF carrier were annealed to produce homoduplexes and heteroduplexes and fractionated on polyacrylamide gels. A 75 bp DNA with no bulged bases served as a control. In a separate experiment, four DNAs were prepared from synthetic oligonucleotides: DNA with an AAG bulge in the one strand, a DNA with a CTT bulge in the other strand, an 85 bp DNA with no deletion in either strand, and an 82 bp DNA with the three-base deletion in both strands. The DNAs were prepared for EM as described elsewhere. In fields of molecules, the number that were straight or bent by less than 30° were scored against those which appeared to have a central kink of 30° or greater, as judged by eye. Number in parentheses indicates the percentage of the total molecules that contain a kink 40–60% from one end of the DNA and in which the kink measures between 70 and 90°. A kink of 0° represents a perfectly straight molecule.
DNAs were seen to have a central kink as compared with the non-bulged controls (Table 1). Examination of the distribution of kinking angles showed that the bulged population contained 5–7-fold more molecules with a central kink of 80 ± 10° than did the control molecules (Figure 2a–c and Table 1).

Examination of the DNAs synthesized to contain just the CTT or AAG bulges and the respective homoduplexes revealed a similar distribution of kinked and straight molecules as seen in the PCR-amplified DNA (Table 1), and the angular distribution of kinks (data not shown) was nearly identical for both.

2.3 Binding of RecA Protein to DNAs Containing Base Bulges and Mismatches

Previous studies have shown that thymine dimers, (37) (6–4) photoproducts, (38) psoralen cross-links, (39) and intercalating drugs (40,41) can promote the nucleation of RecA protein binding on double-stranded DNAs in the presence of adenosine-5'-O-(3-thiotriophosphate) (ATPγS), a poorly hydrolyzed analog of ATP. Other structural variations such as B–Z junctions, (42,43) changes in DNA superhelicity, (44) and an A-T-rich sequence (45) also enhance the binding of RecA protein to double-stranded DNAs. These observations suggest that RecA protein recognizes perturbations in the DNA helix. To test the hypothesis that RecA protein is intimately involved in repair, (46,47) it would be of value to examine the interaction of RecA protein with two lesions that are frequent products of DNA metabolism: bulged bases and single-base mismatches.

Using a nitrocellulose filter binding assay, we examined DNA duplexes containing 1–4-base cytosine bulges and the control DNA. Upon incubation with RecA protein in the presence of ATPγS, DNA with a one-base cytosine bulge showed similar kinetics of RecA binding as compared with DNA lacking a bulge (Figure 3). RecA bound to DNA containing two- or three-base cytosine bulges with a similar kinetics and both showed higher levels of binding compared with the control DNA. DNA containing a four-base cytosine bulge showed even higher binding (~30% more than the control). These results suggest that RecA protein recognizes the perturbation produced by the bulged bases.

Gel electrophoretic studies have demonstrated that single purine bulges in DNA cause greater retardation than single pyrimidine bulges (see above). This suggests that purine bulges introduce kinks of a greater angle into the DNA helix as compared with pyrimidine bulges. To determine whether any correlation exists between the kinking angle and RecA binding, a set of DNAs containing 1–4-base adenine bulges was investigated. Interestingly, we found that RecA bound to DNA containing

![Figure 2](image-url) Angular distribution of kinking angles. The CF DNAs from PCR amplification, a pool of both heteroduplexes (a), both homoduplexes (b), and the 75 bp control DNA (c) were prepared for EM. From the micrographs, the kinking angle in each kinked DNA was measured, in addition to its position relative to the DNA ends. For those molecules in which the kink was within 10% of the center, the angle of the kink was plotted. Approximately 100 bent molecules for each sample were measured. A cut-off of angles less than 30° was imposed by eye.
Although a single-base mismatch does not kink DNA (see above), RecA protein showed preferential binding to DNAs containing certain single-base mismatches (Figure 4a and b). Moreover, DNAs containing single-base mismatches flanked by A-T bps showed equal or better efficiency of RecA binding than when the mismatches were flanked by G-C bps. Among the eight possible mismatches flanked by A-T bps, the A-C, A-A, G-A and C-C mismatches promoted RecA protein binding in presence of ATPyS. Interestingly, an A-C mismatch flanked by A-T bps in a 28 bp DNA facilitated the binding of RecA protein to the same high level as when the 28 bp DNA contained a four-base cytosine bulge (Figure 4c). Chemical probing techniques were used to examine the structure of DNA within the RecA filament. It was found that upon binding of RecA protein, the DNA helix became accessible over at least 14 bp and the degree of chemical modification agreed with the binding efficiency of RecA protein (Figure 5).

2.4 Summary

Gel electrophoretic studies have shown that DNAs containing 1–4-base bulges exhibit decreased mobilities in polyacrylamide gels, suggesting that bulged bases produce a kink in the DNA helix. The degree of kinking depends on the number of bases in the bulge, the base composition of the bulge, and the flanking bps. Visualization of a DNA containing a three-base bulge by EM has directly demonstrated kinks created by bulges and provided a measure of the distribution of the kinking angles. The binding of RecA protein to short DNAs containing lesions provides a sensitive means to detect perturbations in the helix. Binding of RecA protein to bulged DNA is influenced by the conformation of the bulged bases and by the kinking angles, which in turn are determined by the type and number of bases in the bulge. Although a single-base mismatch does not produce a kink in the DNA helix, we have found that certain single-base mismatches, for example an A-C mismatch flanked by A-T bps, facilitate the binding of RecA protein with the same high level as a four-base cytosine bulge. When these DNAs containing mismatches or base bulges were probed with chemicals, the degree of chemical modification agreed with the binding efficiency of RecA protein.

These studies provide critical structural information about DNAs containing bulges and mismatches. It will be important to correlate the structural information of these damaged DNAs with the relative rates of their repair by the methyl-directed mismatch repair system. Further, the binding of RecA to damaged DNA may facilitate recombinational repair by increasing the local concentration of RecA protein at the site of the damage. Therefore, the efficiency of RecA binding should also be taken into consideration in the overall repair/mutagenesis outcome of these damaged DNAs.

Figure 4 Comparison of RecA binding to bulged and mismatched DNAs. (a) Sequences of DNAs containing eight possible mismatches (positions indicated by X-Y) with two different flanking bps (A-T or G-C) and the control DNA (the lower sequence) are shown. (b) The 40 min time points of RecA binding to all 16 mismatched DNAs and the control DNA. The solid bars refer to mismatches flanked by G-C bps and the hatched bars to mismatches flanked by A-T bps. (c) DNAs containing: one-base cytosine bulges (C1), four-base cytosine bulges (C4), A-C mismatch flanked by A-T bps (A-C), G-T mismatch flanked by A-T bps (G-T), and the control DNA were compared using the filter binding assay as in Figure 3.

Figure 5 Diethyl pyrocarbonate (DEP) probing of DNAs containing A-C mismatches. DNAs containing an A-C mismatch flanked by A-T bps (lanes 1 and 2) or flanked by G-C bps (lanes 3 and 4) and the control DNA (lanes 5 and 6) were incubated without RecA protein (lanes 1, 3 and 5) or with RecA protein (lanes 2, 4, and 6) for 40 min at 37°C. DEP was added at 37°C for an additional 10 min and the modified DNAs were cleaved with piperidine and analyzed by electrophoresis in a 20% polyacrylamide–8.3 M urea gel. The positions of the 32P label (+), mismatched bp (boxed) and DEP-cleaved adenines (underlined) are indicated. In the autoradiogram, the mismatched adenines are indicated by arrows and a G-specific cleavage reaction of the control DNA serves as markers (M).

3 TRINUCLEOTIDE REPEATING DNA, NUCLEOSOME POSITIONING, AND HUMAN GENETIC DISEASES

DNA in the human cell is packaged progressively beginning with the most elementary particle termed the nucleosome. In a nucleosome 146 bps of DNA are wrapped 1.75 times around a protein core consisting of an octamer of the core histones (H2a, H2b, H3, H4). Each nucleosome is spaced in the human cell by ~50 bps of linker DNA to which histone H1 and other factors bind. This “string of beads”, folded into larger structures by the action of H1, is eventually condensed into the metaphase
chromosomes observed by light microscopy. Different DNA sequences have been found to show differences in their affinity for wrapping around the core histone octamer and thus to be assembled into chromatin.

The ability of a variety of DNA sequences to form nucleosomes has been studied extensively. Repeated tracts of 4–6 adenines in-phase with the helix produce sequence-directed bends, and bent DNA preferentially assembles into nucleosomes, presumably owing to the greater ease of wrapping of the DNA about the histone core. The sequence element (A/T)$_3$NN(G/C)$_3$NN creates an anisotropically flexible wedge which also facilitates wrapping DNA about the histone octamer. The 5S RNA gene from several species contains such flexible wedges and exhibits very strong sequence-directed nucleosome positioning. Indeed, Shrader and Crothers were able to create synthetic nucleosome positioning elements in which nucleosome formation was energetically favored over the 5S DNA by spacing up to 10 wedges in-phase with the helix.

Sequences also exist that inhibit nucleosome formation and in vivo such sequences, were they to occur in promoter or enhancer regions, could play an extremely important role in maintaining access to the DNA. DNA–RNA hybrids, left-handed Z-DNA, and DNA containing poly(dA : dT) runs have all been shown to exclude nucleosome formation in vitro. Iyer and Struhl found that poly(dA : dT) tracts in the yeast his 3 promoter stimulate Gcn4-activated transcription in vivo owing to nucleosome exclusion and increased accessibility of Gcn4-binding sites.

Described here are our findings that show that the expanded triplet sequences characteristic of DM and FraX, the two most common human triplet diseases, bracket the known range of affinities of DNAs for nucleosome assembly. While long tracts of repeating CTG triplets (expanded in DM) form the most stable known naturally occurring nucleosomes, long tracts of repeating CCG triplets (expanded in FraX) resist nucleosome assembly. In addition, methylation of the CCG repeats further represses the already weak ability of these (CCG) DNAs to assemble into chromatin. The physical basis for exclusion of nucleosomes by DNA containing long tracts of CCG repeats has been probed in experiments with model DNAs. Results from these studies revealed a new class of repeats in eukaryotic promoters, [(C/G)$_3$NN]$_n$, which may serve to loosen chromatin structure in the promoters of TATA-less genes.

3.1 CTG Repeats in Myotonic Dystrophy

DM is an autosomal dominant disease and the defect has been mapped to chromosome 19. Two genes at the DM locus [the myotonic dystrophy protein kinase (DMPK) and the myotonic dystrophy locus-associated homeodomain protein (DMAHP) genes] have been shown to be affected by the expanded CTG repeat which is located in the 3’ untranslated region of the DMPK gene and is about 1 kb from the major transcription start site of the DMAHP gene (Figure 6). A block of 5–37 CTGs is frequently found in normal individuals, while DM patients with mild symptoms have triplet blocks of 50–80 repeats, and expansions from 100 to several thousand repeats can be found in individuals with full-blown symptoms. DM patients are heterozygous with only one of the two alleles containing an expanded triplet block, since homozygotes are rare and lethal. To date, the pathogenic mechanism of DM is not well understood.

3.1.1 Nucleosome Positioning by Long CTG Repeats

Knowledge that the threshold for the triplet diseases frequently approximates the amount of DNA in a nucleosome, and the general understanding that any short repeating sequence may amplify sequence signals for nucleosome positioning or exclusion, led us to examine the ability of long repeating tracts of (CTG)$_n$ to assemble into chromatin. This work was carried out using a simple but well established method of chromatin assembly involving mixing DNA with purified histone octamers (H2a, H2b, H3, H4) in 2 M NaCl followed by a progressive lowering of the salt concentration to 0.6 M or less by stepwise dilution or dialysis. In the approach used in Wang et al., a minimal amount of histone octamers was used such that each DNA would on the average, contain only a single assembled nucleosome. This simplified measurement of the nucleosome position since the foreshortening due to multiple nucleosomes would have greatly complicated analysis. In this study, direct EM was utilized to measure the position of several hundred individual nucleosomes along single DNAs and the data were summed to create a nucleosome positioning map. To distinguish one end of the linear DNA from the other, one DNA end was labeled with a biotin–streptavidin tag.
NUCLEIC ACIDS STRUCTURE AND MAPPING

For such analysis it was important to also consider the effects of magnesium and supercoiling of the template DNA. Numerous DNA structural transitions are facilitated by negative supercoiling or influenced by heating in the presence of magnesium. A supertwisted plasmid, pSH2 isolated from *E. coli*, containing 130 CTG repeats derived from a DM patient was treated with magnesium and heat and then reconstituted into chromatin. The DNA was then linearized to place the CTG triplets in pSH2 between 32 and 43 map units along the DNA (Figure 7a and b). The resulting nucleosome map (Figure 8a) revealed that 48% of all the nucleosomes were present in the region between 30 and 45 map units. In contrast, the map for the Bluescript vector lacking the CTG insert (Figure 8b) showed a uniform distribution of nucleosomes over the length of the DNA with only 10% of the nucleosomes present in the region between 30 and 45 map units. The use of linear or supercoiled DNA that had not been treated with heat or magnesium still resulted in 29% of all nucleosomes localized to the triplet repeat (Figure 8c and d). Further analysis using a set of six pUC19-based plasmids (pretreated with heat and magnesium) containing 26–250 contiguous CTG triplet repeats showed that as the size of the triplet block increased in size the efficiency of nucleosome formation at the repeats also increased up to a repeat size of 180. These data are summarized in a normalized form in Figure 9.

These data provided the first direct evidence that repeating CTG triplets can serve as a strong nucleosome-positioning element. Indeed, this increase in strength of nucleosome formation occurred over the range where the triplet blocks change from normal, to the intermediate, to disease-causing. The EM observations therefore suggest that expanded blocks may create unusually stable nucleosomes that could alter local chromatin structure. Microscopy, however, was unable to provide precise measurements of the strength of the CTG repeat blocks as nucleosome positioning elements, data that would be essential to models based on these observations.

A method for measuring the strength of nucleosome positioning elements has been developed by Shrader and Crothers,\(^51\) termed competitive nucleosome reconstitution (Figure 10a). In this assay, a small amount of the specific DNA to be tested (0.1 µg) is labeled with \(^{32}\)P and then mixed with a 200-fold excess of unlabeled calf thymus DNA (20 µg) and ~5 µg of calf thymus histone octamers\(^50\) in a solution containing 2 M NaCl. The salt is slowly lowered to 0.1 M NaCl and the mixture is electrophoresed on a 5% polyacrylamide gel to separate free DNA from the nucleosome-assembled DNA. The amount of DNA in each band is quantified. Usually three or four separate but identical experiments are carried out for each set of DNAs. In such studies, a sequence found in the *Xenopus borealis* somatic SS RNA gene is frequently used as a standard against which other sequences are measured. This SS element was previously the strongest
known natural nucleosome positioning element. Using this method, we\cite{74} compared DNAs containing 75 and 130 CTG repeats to the *X. borealis* somatic 5S RNA gene. In such studies it is important that the DNAs being compared are of the same size. Thus two pairs of DNAs, ~285 and ~450 bp in size, were compared.

The results of such an analysis for the sets of DNAs of ~285 and ~450 bp are shown in Figure 10(b) and (c). The nucleosome-assembled DNA appears as a retarded band. One major retarded band was observed in both 5S RNA gene samples while two retarded bands were found in the ~285 bp (CTG)$_{75}$-containing DNA and possibly three closely spaced retarded bands were present in the ~450 bp (CTG)$_{130}$-containing DNA. The multiple retarded bands represent DNAs associated with two or three nucleosomes. The results revealed that the ratio of the fraction of the nucleosome-assembled DNA to free DNA is 5.6 ± 0.4-fold higher in the DNA containing the (CTG)$_{75}$ block as compared with the 5S RNA gene. The ~450 bp DNA containing the (CTG)$_{130}$ block is 8.7 ± 0.7 fold stronger than the 5S RNA gene (472 bp) in nucleosome assembly.

These assays allow one to calculate the free energy difference for nucleosome formation. The difference in
free energy between the (CTG)_{75} DNA and the 5S RNA gene was found to be 1015 ± 43 cal mol⁻¹ and for the (CTG)_{130} DNA the difference was 1276 ± 45 cal mol⁻¹. In Figure 11, these results are combined with data obtained by Shrader and Crothers⁵¹ and further work described below. To match the different studies, the free energies for the vector DNA for each set of experiments was taken as zero.

These studies demonstrated that when CTG repeat blocks grow to sizes of \( n \geq 75 \) they become the strongest known natural nucleosome positioning elements, and (at \( n = 130 \)) are nearly nine times stronger than the 5S element. The difference in binding free energy between the strongest and average DNA elements is seen to span a range of \( \geq 100 \)-fold. However, the total energy difference measured in high salt is relatively low, 3 kcal mol⁻¹.⁷⁰ Hence whether or not such differences measured in high salt would be physiologically relevant remained in question. In the cell, at physiological ionic strength and in the presence of histone H1 and nucleosome assembly factors, these differences could be great enough to dictate nucleosome positioning. The strongest evidence that these free energy differences do represent physiologically important differences was to come from model studies of the CCG triplet repeat from Fragile X expansions as described below.

Godde and Wolffe⁷⁸ also examined nucleosome assembly on (CTG)ₙ repeats by competitive nucleosome reconstitution and mapped translational and rotational positions by nuclease and hydroxyl radical cleavage. They confirmed the observation of Wang and Griffith⁷⁴ that CTG repeats create sites for preferential nucleosome assembly. However, they did not observe the increase in efficiency of nucleosome assembly with increasing size of the repeat from 10 to 55 and 62 copies, which may be too short to display the effect. Probing of rotational position demonstrated a clear 10–11 bp repeating pattern over the DNA containing six copies of CTG repeat and the pattern remains similar in (CTG)₅₅ DNA. Moreover, the (CTG)₆-containing DNA favors a single translational position with the CTG sequence bordering the nucleosomal dyad whereas the (CTG)₅₅ DNA showed several nucleosome positions.

3.1.2 Implications of Arrays of Hyperstable Chromatin at the Myotonic Dystrophy Locus

The in vitro nucleosome reconstitution studies described above clearly show that repeating CTG triplets can generate very unusual chromatin structure. When the repeat tracts grow into the size range in which DM disease symptoms appear, these repeat tracts can generate chromatin segments with stabilities that are possibly nine times greater than the previously strongest known natural nucleosome positioning element, the 5S DNA. Although the precise physical reason why such repeating triplets generate such highly stable chromatin remains unclear, a number of possible biological implications of the appearance of such abnormally stable chromatin segments are worth mentioning.

Otten and Tapscott⁶⁹ have carried out in vivo mapping of nucleosome hypersensitive sites with DNA samples of fibroblasts and myoblasts from three unrelated DM patients in which the DM alleles are heterozygote and the expansion is \( \sim 6 \) kb. Compared with the observations from an unaffected individual and the wild-type allele, the expanded allele showed loss of the DNAse I hypersensitive site located just 3’ of the CTG repeat (indicated by an arrowhead in Figure 6) and resistance to restriction endonuclease cleavage adjacent to the DNase I hypersensitive site. Recently, this hypersensitive site has been mapped to an enhancer region which regulates the expression of the DMAHP gene.⁷⁹ In cells of DM patients with a loss of the hypersensitive site, the amount of DMAHP transcript was reduced compared with the controls and the amount of transcript from the expanded allele was also greatly lowered compared with that from the wild-type allele. These results elegantly demonstrated that the expanded CTG repeat produces an altered chromatin structure, possibly resulting from the strong nucleosome positioning by the CTG repeat. The altered chromatin structure might suppress the transcription of the DMAHP gene which leads to the pathogenesis of DM.

Furthermore, the appearance of a segment of hyperstable chromatin could in itself promote further expansion...
of the triplet tract. During the replication of eukaryotic DNA, the replication machinery must remove the DNA template from the histone octamer prior to, or possibly in concert with, the helicase action that separates the two DNA strands. Were the replication machinery to be severely hindered in this action by the presentation of an array of hyperstable nucleosomes, then the likelihood of polymerase slippage as the replication fork transited the triplet tract would be expected to be much greater.

As arrays of hyperstable nucleosomes might impede the replication machinery, they might also slow or stop
and with each additional nucleosome added the effect of the array of hyperstable nucleosomes increases greatly that as the CTG tract grows, the size and thus strength of the tract could exert its biological effect. It could be imagined that the most attractive models of how this expanded CTG tract in the DMPK gene is also in the upstream region of the DMAHP gene, (73,75) these presents one of the most attractive models of how this expanded CTG tract could exert its biological effect. It could be imagined that as the CTG tract grows, the size and thus strength of the array of hyperstable nucleosomes increase greatly and with each additional nucleosome added the effect of this very unusual hyperstable chromatin boundary could grow from just interference with transcription of the DMAHP gene to interference also with the DMPK gene and finally to interfering with all three genes including the upstream 59 protein gene. The clinical observations that the presentation of DM differs depending on the size of the CTG tract may reflect a progressive involvement of additional genes as the tract increases in size.

3.2 Expanded CCG Repeats in Fragile X Syndrome and Folate-sensitive Fragile Sites

Fragile sites are chromosomal loci that stain poorly, contain gaps and are frequent sites of DNA strand breakage. Thus they represent regions of unstable chromatin structure. More than 100 separate fragile sites have been identified in the human genome, classified as common or rare, and, further, they are divided according to the agents used to identify them. (86) Fragile sites are highly conserved and appear to have played key roles in the stepwise evolution of primate chromosomes. Recent work suggests that they are major sites of drug-induced chromosomal amplification. (89) A number of fragile sites have been cloned, the majority being members of the class termed rare, folate-sensitive sites which are seen

**Figure 11** Comparison of free energies derived from several nucleosome positioning sequences. Data which are at the left of the free energy scale bar were adapted from Shrader and Crothers. The sequence of the 20 bp anisotropically flexible wedge is TCGGGTTAGAGCCTGTAAC. Results from studies of Wang and Griffith (74–77) are listed at the right side of the bar with the free energies of the vector DNA (pUC19 fragments) defined as zero cal mol

transcription complexes. When RNA polymerase stalls on DNA the nascent RNA chain is frequently cleaved, inactivating the RNA. Examination of transcription of the DMPK gene has provided conflicting results regarding the amount of DMPK transcript expressed by the expanded DM allele. Whether or not expanded CTG tracts in DM protein kinase gene result in lowered mRNA levels is currently in question. It is possible that such an effect may only be evident when the tracts become longer than those investigated in some of the studies reported to date.

Finally, a global effect of arrays of hyperstable nucleosomes may be to generate domains of inactive chromatin. Such elements could inactivate genes either upstream or downstream of the domain and possibly over distances of many kilobases. Domains generated by an array of hyperstable nucleosomes would be similar to chromatin barriers that have been shown to silence genes moved into their proximity. Given the findings that the CTG tract in the DMPK gene is also in the upstream region of the DMAHP gene, (79,87) this presents one of the most attractive models of how this expanded CTG tract could exert its biological effect. It could be imagined that as the CTG tract grows, the size and thus strength of the array of hyperstable nucleosomes increase greatly and with each additional nucleosome added the effect of this very unusual hyperstable chromatin boundary could grow from just interference with transcription of the DMAHP gene to interference also with the DMPK gene and finally to interfering with all three genes including the upstream 59 protein gene. The clinical observations that the presentation of DM differs depending on the size of the CTG tract may reflect a progressive involvement of additional genes as the tract increases in size.
by light microscopy when cells are exposed to a folate starvation regime. Sequence analysis of five rare, folate-sensitive sites, FRAXA, FRAXE, FRAXF, FRA16A, and FRA11B, revealed long blocks of repeating CCG triplets together with the frequent methylation of nearby CpG islands.\(^{90-96}\) Another fragile site, FRA16B, was sequenced and found to involve a highly A/T-rich element demonstrating that not all fragile sites involve repeating CCG triplets. Expansion of the triplet block in the 5’ untranslated region of the FMR-1 gene\(^{97,98}\) at FRAXA from 20 to 50 repeats in most individuals to >200 CCG repeats has been linked to the FraX (see below).

The expanded triplet block is the site of preferential breakage at FRAXA.\(^{90,91}\) The FRAXE site on the X chromosome\(^{93}\) is correlated with a rare form of mental retardation, and the FRA11B site is associated with Jacobsen’s syndrome. Here, a portion of the long arm of chromosome 11 is lost, implying a link between this fragile site and chromosome breakage.\(^{96}\) FRAXF and FRA16A are apparently without disease phenotype.\(^{94,95}\)

FraX was named for the presence of a rare, folate-sensitive fragile site on the X chromosome (FRAXA) whose appearance correlates with the disease.\(^{97,98}\) In contrast to DM, the FMR-1 gene is likely the only gene

![Figure 12](image_url)

**Figure 12** Distribution of nucleosomes assembled on closed, circular (a) pRW3376 containing the (CCG)\(_{76}\) repeat block and (b) pT7 blue vector as a control; (c) p(CCGNN)\(_{48}\) plasmid and (d) pGEM3zf(+) vector as a control. Nucleosome assembly and EM analysis were performed as described.\(^{75,76}\) At least 100 DNA molecules containing single nucleosomes were photographed, the position of each nucleosome from the streptavidin-labeled end (filled circle) was measured, and a histogram was generated (with DNA length broken into 20 slices and each percentage of length equivalent to 1 map unit) showing the location of the nucleosomes along the DNA. The positions of the (CCG)\(_{76}\) sequence in pRW3376 and the (CCGNN)\(_{48}\) sequence in p(CCGNN)\(_{48}\) are indicated.
involved in FraX. Studies of the FMR-1 gene have also shown reduced transcription from this locus in FraX patients<sup>99</sup> and rare FraX cases are seen in which there has been a deletion or point mutation in the FMR-1 protein, pointing to loss of protein function as a cause of the disease.<sup>100</sup> Moreover, the severity of the disease has been shown to be directly related to the size of the triplet repeat and also the purity of the repeat tract. Thus, moderate-sized pure CCG repeat tracts are more deleterious than longer repeat tracts containing interruptions. Finally, there is also a strong correlation between the severity of the disease symptoms and the level of methylation of the region. Hence any model for the molecular basis of FraX will have to account for these observations.

### 3.2.1 Nucleosome Exclusion by Repeating CCG Tracts

The discovery of hyperstable nucleosome formation by long tracts of CTG triplet repeats spurred a parallel analysis of DNAs containing long CCG triplet repeat tracts. This work was further impelled by the knowledge that the fragile sites containing CCG triplet blocks exhibit properties of unstable chromatin suggesting that significant effects on chromatin structure due to the presence of these repeats might be found. Indeed it had been speculated earlier<sup>101</sup> that fragile sites may result from the inability of DNA to fold compactly during metaphase.

In the work of Wang et al.,<sup>75</sup> a series of plasmids containing different sized tracts of repeating CCG triplets were employed. The plasmid pRW3376 contains 76 tandem CCG repeats<sup>102</sup> and this DNA was reconstituted with purified histone octamers, linearized, and one DNA end labeled with streptavidin to place the (CCG)<sub>76</sub> repeat block between 18% and 26% from the marked end in a manner similar to that illustrated in Figure 12(a). A nucleosome map was then prepared. Inspection of the data showed that only 2.6% of the DNAs had a nucleosome located between 15 and 20 map units from the marked end and no molecules had nucleosomes between 20 and 25 map units. This was in contrast to other segments of 5 map units length which showed from 5% to 10% of the DNA with nucleosomes assembled. The parent vector showed no regions of nucleosome exclusion (Figure 12b). These direct EM observations provided the first evidence that repeating CCG triplets could lead to nucleosome exclusion in contrast to nucleosome positioning observed with repeating CTG triplets. Control experiments showed that legitimate nucleosomes were being formed on normal sequence DNA in the same reactions.

Competitive nucleosome reconstitution was then used in this study to measure the energetics of nucleosome formation for DNA fragments containing CCG repeats of increasing size (Figure 13a and b). The ratio of nucleosome assembled DNA to free DNA for a pUC19 fragment and similar length fragments containing 10, 24, 54, and 76 CCG repeats was determined. It was found that as the length of the repeat block increased, the efficiency of nucleosome assembly decreased. Whereas a 261 bp DNA containing 10 tandem CCG repeats showed a 1.4-fold lower efficiency (30% decrease) in nucleosome assembly relative to the pUC19 fragment, the fragment containing 76 tandem CCG repeats was 2.6 ± 0.4-fold less effective (62% decrease), corresponding to a 564 ± 89 cal mol<sup>-1</sup> difference in free energy (Figure 11). Compared with the free energy value for a similar sized DNA containing 75 CTG repeats (see above), this amounts to a 40-fold difference between the two repeating triplet DNAs. These observations clearly paralleled the in vivo observation of fragile sites being regions of unstable chromatin.

While the physical basis for repeating CTG triplets forming hyperstable nucleosomes remains unclear, experiments with model variants of the CCG motif provided clues as to why this expanded triplet may exclude nucleosomes and, further, revealed a possible function for these motifs in eukaryotic genomes.

### 3.2.2 Model Studies Involving the Repeat [(C/G)<sub>3</sub>NN]<sub>n</sub>

Considering the properties of the sequence motif in the 5S RNA gene, (G/C)<sub>3</sub>NN(A/T)<sub>3</sub>NN, which forms very strong nucleosomes,<sup>51,103</sup> we postulated<sup>76</sup> that DNA containing long repeats in the form of (G/C)<sub>3</sub>NN(G/C)<sub>3</sub>NN might exclude nucleosomes. This latter motif differs from the 5S RNA gene element in that each time minor groove compression is required, the DNA presents the histone octamer with a wedge that favors bending into the major groove. Shrader and Crothers<sup>51</sup> had noted that a triplet of As or Ts preferentially bends into the minor groove of DNA whereas a triplet of Gs or Cs bends preferentially into the major groove. Thus DNA containing a nucleosome-sized tract of repeating CCGNN pentanucleotides which is a member of the (G/C)<sub>3</sub>NN(G/C)<sub>3</sub>NN motif family should resist nucleosome formation. Pure repeating CCG triplet tracts are also a member of this general family and if nucleosome exclusion were observed for DNA containing repeating CCGNN pentanucleotides this would provide an explanation for nucleosome exclusion by repeating CCG triplet tracts.

To test the hypothesis that long tracts of (G/C)<sub>3</sub>NN repeats will exclude nucleosomes, three pGEM3zf(+) based recombinant plasmids, p(CCGNN)<sub>12</sub>, p(CCGNN)<sub>24</sub>, and p(CCGNN)<sub>48</sub> containing, respectively, 12, 24, and 48 tandem copies of the CCGNN repeat with the NS varied and rich in As and Ts, were generated. EM was then utilized together with in vitro nucleosome reconstitution onto supertwisted p(CCGNN)<sub>48</sub> plasmid...
DNA STRUCTURES OF BIOLOGICAL RELEVANCE, STUDIES OF UNUSUAL SEQUENCES

Figure 13 Competitive nucleosome reconstitution with (a, b) CCG and (c, d) CCGNN containing DNAs. (a) Autoradiogram of a competitive nucleosome reconstitution experiment. Lane 1, the 262 bp pUC19 fragment; lanes 2–5, DNA fragments containing 10, 24, 54, and 76 CCG repeats respectively. Note: the (CCG)$_{54}$ and (CCG)$_{76}$ repeat blocks contain AGG and CAG interruptions.$^{102}$ (b) Dependence of nucleosome assembly on the length of the repeat block. (c) Autoradiogram of a competitive nucleosome reconstitution experiment. Lane 1, the 262 bp pUC19 fragment; lanes 2–4, DNA fragments containing 12, 24, and 48 CCGNN repeats, respectively. (d) Dependence of nucleosome assembly on the length of the repeat block. DNA preparation, reconstitution of the fragments with histones, and gel electrophoresis were as described elsewhere.$^{75,76}$ Each DNA was reconstituted in three separate but identical experiments, and the fraction of DNA in the nucleosome-assembled and nucleosome-free DNA bands was measured by a PhosphorImager.

DNA to examine the propensity of the inserts to assemble into nucleosomes as described above. Subsequent to assembly the DNA was linearized placing the CCGNN block in p(CCGNN)$_{48}$ between 27% and 34% from the tagged end. Analysis revealed strong nucleosome exclusion over the (CCGNN)$_{48}$ insert with only 2% of all nucleosomes mapped located between 25 and 35 map units whereas in other segments of this length ~10% or more of the DNA contained a nucleosome (Figure 12c). In contrast, the parent pGEM3zf(+) vector showed no regions of strong nucleosome exclusion (Figure 12d).

Competitive nucleosome reconstitution assays were then employed as described$^{74}$ to quantify the degree of nucleosome exclusion over the insert in these plasmids. DNAs ~260 bp in length containing (CCGNN)$_{n}$ blocks of 12, 24, or 48 repeats were generated. As the length of the CCGNN repeat sequence increased from 12 to 48 repeats within a ~260 bp segment, the ability of the DNA to exclude nucleosomes increased in proportion to the length of the repeat block (Figure 13c and d). Analysis showed that the 268 bp DNA containing the (CCGNN)$_{48}$ repeat is 4.9 ± 0.6-fold less efficient in nucleosome assembly than the same sized pUC19 fragment. Indeed,
NUCLEIC ACIDS STRUCTURE AND MAPPING

a 261 bp DNA containing 12 tandem CCGNN repeats assembled nucleosomes 94% as efficiently as a 262 bp pUC19 fragment. When these results were combined with results from earlier studies, it was estimated that the (CCGNN)$_{48}$ repeat block is ~78-fold less efficient than a similar length block of repeating CTG triplets. The difference in free energy between the (CCGNN)$_{48}$ fragment and the pUC19 DNA is 937 ± 79 and ~2600 cal mol$^{-1}$ relative to the CTG$_{75}$ repeating element (Figure 11).

Based on the findings described above, a computer search was carried out using the GenBank database to examine the prevalence of the general [(G/C)$_3$NN]$_{48}$ motif. Searches against 240 bp of a [(G/C)$_3$NN]$_{48}$ continuously repeating sequence revealed many matches, and 75 examples showed ≥85% sequence match over 200 bp of this motif (Table 2). Many of these were present in or near the control regions for eukaryotic genes. Of the 75 with the greatest number of sequence matches, 31 genes were noted to contain the (G/C)$_3$NN motif in the 5′ region upstream of the coding sequences. Such regions would be loci where nucleosome exclusion would be expected to provide favored access to sequence-specific proteins engaged in the regulation of gene expression. It was also observed that at least 20 of these 31 genes lack a TATA box in the promoter region and are “TATA-less” genes. In two of these genes, the 5′ regions have been mapped for nuclease hypersensitive sites. The −530 to −300 nucleotide (nt) upstream control region of the human dihydrofolate reductase gene contains the [(G/C)$_3$NN]$_{48}$ motif (with 87% sequence match) and this overlaps with a hypersensitive region mapped in vivo. In the gene for the human ETS-2 nuclear phosphoprotein, there is a sequence upstream of the gene between nts

$^a$ At least 75 genes in the GenBank were found to have ≥85% sequence matches to [(G/C)$_3$NN]$_{48}$.

$^b$ The first number indicates the number of bases showing sequence matches with [(G/C)$_3$NN]$_{48}$ and the second number refers to the length of this sequence.
-195 and +45 containing the \([\text{(G/C)}_3\text{NN}]_{48}\) motif (with 86\% sequence match). The promoter region of this gene maps between nts -159 and +141. Here studies of nucleosome positioning in the promoter region using S1 nuclease revealed a hypersensitive region from nts -150 to -50. This 100 bp hypersensitive region exactly co-maps with the region containing the \([\text{(G/C)}_3\text{NN}]_{48}\) motif.

The discovery of long DNA sequences in the human genome with strong matches to the \([\text{(G/C)}_3\text{NN}]_{48}\) motif and the finding that in two cases these sites correspond to regions shown by others to be spared of nucleosomes have several important implications. First, it provides the most compelling evidence to date that the differences in free energy measured in vitro in high salt (which are in the range of a few kilocalories) are biologically significant. Indeed, the two most common human triplet diseases, DM and FraX, involve triplet expansions which bracket the range from strongest to weakest nucleosome assembly elements. The second and broader implication of this work is that the sites composed of long repeats of \((\text{C/G})_3\text{NN}\) pentanucleotides present in the 5' control regions of genes lacking TATA boxes may be a common occurrence in eukaryotic genomes. Here these elements would serve to loosen the chromatin structure, providing access to the DNA for the transcriptional machinery.

In FraX, AGG interruptions have been shown to stabilize the CCG repeats against expansion. Comparison of the data presented in the papers of Wang and Griffith (Figure 13a–d) reveal a greater resistance to nucleosome assembly for the \((\text{CCGNN})_{48}\) DNA in contrast with the similar sized \((\text{CCG})_{76}\) block. This suggests that the interruptions in the latter DNA may significantly impair the ability of this overall element to exclude nucleosomes. Thus the well characterized effects of these interruptions could be to moderate the ability of these long repeat blocks to alter the local chromatin structure.

### 3.2.3 Methylation of CCG Enhances Nucleosome Exclusion

In eukaryotic cells, methylation of CpG dinucleotides by DNA methyltransferase has been found to inhibit directly gene expression. This enzyme places a methyl group at C-5 of the cytosine residues of 5'CpG3' dinucleotides and has been shown to play an important role in embryonic development. Repression of genes by DNA methylation has been studied extensively and might serve as a regulatory step to turn off a gene in order to distinguish alleles of different parental origins (genomic imprinting), or when a gene is not needed, or is subject to dosage compensation (X chromosome inactivation).

The inhibition of transcription by methylation may be mediated by the binding of a methyl-CpG binding protein to DNA sequences containing methylated CpG dinucleotides. In the context of FraX, Sutcliffe et al. have demonstrated that long CCG repeats alone cannot repress FMR-1 transcription whereas DNA methylation is required for transcriptional repression of the FMR-1 gene. Furthermore, DNA demethylation by 5-azadeoxycytidine has been shown to reactivate the FMR-1 gene in patient cell lines. These observations prompted studies to determine how methylation of the CCG tracts would influence their already poor ability to assemble into chromatin.

SssI methylase was used in our studies to place a methyl group on the C-5 position of cytosines within the 5'CpG3' dinucleotides. Two sets of experiments were carried out in this study. In one, a 262 bp fragment from pUC19 was compared with a 282 bp DNA containing 76 tandem CCG repeats. In the second, the same pUC19 fragment was compared with a 268 bp fragment containing 48 contiguous CCGNN repeats as described above. The number of possible methylation sites for the pUC19 fragment, the CCG-containing DNA, and the CCGNN-containing DNA is 40, 164, and 102, respectively. Here the level of methylation was estimated from the cleavage pattern by the methylation-sensitive restriction endonuclease HhaI. Competitive nucleosome reconstitution was then used to measure the energetics of nucleosome formation over the CCG and CCGNN repeats as compared with a pUC 19 DNA of the same size. This analysis (Figure 14a–c) showed that DNA methylation had no measurable influence on nucleosome formation for the pUC 19 fragment, an observation noted in several previous studies.

In contrast, the \((\text{CCG})_{76}\) DNA methylated at 85\% of the available sites was 2.0 ± 0.2-fold less effective in nucleosome assembly compared with the same \((\text{CCG})_{76}\) DNA fragment that was unmethylated, and 4.4 ± 0.4-fold less effective relative to the pUC19 fragment. The difference in free energy between the methylated (at 85\%) and the unmethylated \((\text{CCG})_{76}\) DNA is 405 ± 44 cal mol\(^{-1}\). With respect to the pUC19 DNA, the methylated (at 85\%) \((\text{CCG})_{76}\) DNA is 880 ± 54 cal mol\(^{-1}\) less favorable (Figure 11). Similar results were obtained when the pUC19 fragment was compared with the 268 bp fragment containing 48 tandem CCGNN repeats. The \((\text{CCGNN})_{48}\) DNA fragment methylated at 62\% of the available sites was 2.1 ± 0.3- and 12.6 ± 1.6-fold less effective in nucleosome formation compared with the unmethylated \((\text{CCGNN})_{48}\) DNA and the pUC 19 fragment, respectively (Figures 11 and 14b). These efficiencies correspond to 425 ± 93 and 1498 ± 75 cal mol\(^{-1}\) differences in free energy, respectively. The greatest difference was observed with a fragment.
Figure 14 Competitive nucleosome reconstitution with methylated DNAs. Competitive nucleosome reconstitution was carried out comparing (a) a 262 bp pUC19 fragment with a 282 bp DNA containing 76 tandem CCG repeats at three different levels of methylation. Lanes 1–3, the pUC19 fragments methylated at 0, 95, and 100% of the available sites respectively; lanes 4–6, the (CCG)\textsubscript{76} DNA fragment methylated at 0, 45, and 89% of the available sites respectively. (b) Comparison of the 262 bp pUC19 fragment to a 268 bp DNA containing 48 tandem CCGNN repeats at three different levels of methylation. Lanes 1–3, the pUC19 fragments methylated at 0, 36, and 43% of the available sites respectively; lanes 4–6, the (CCGNN)\textsubscript{48} DNA methylated at 0, 12, and 62% of the available sites respectively. (c) Dependence of nucleosome assembly on methylation of CpG dinucleotides. Data from the competitive nucleosome reconstitution experiments are shown. Each DNA was reconstituted in three separate but identical experiments, and the fraction of DNA in the nucleosome-assembled and nucleosome-free DNA bands was measured by PhosphorImager scanning.

containing the (CCGNN)\textsubscript{48} repeat block. When this DNA was highly methylated, it was nearly 13-fold less effective in nucleosome assembly compared with a mixed sequence DNA of the same size.

Wang and Griffith\textsuperscript{[77]} presented a general model for the role of CCG repeats and methylation in the generation and expression of fragile sites containing these triplet repeats. It was proposed that long repeating CCG triplet blocks inhibit chromatinization of DNA which would increase the accessibility of these regions to DNA methyltransferase. Next, methylation of the repeats would further repress chromatinization and make the DNA more available for binding by methyl CpG binding proteins which have been shown to repress transcription.

The net effect of these changes would be the expression of the fragile site and the genetic repression of nearby genes such as the FMR-1 gene.

Godde et al.\textsuperscript{[121]} also examined the ability of CCG repeats to assemble into nucleosomes and found that DNA containing a short CCG repeat (13 copies), upon methylation, showed preferential nucleosome assembly with an affinity similar to that of the (CTG)\textsubscript{10}-containing DNA. However, in a longer CCG DNA (74 copies), methylation represses the ability to assemble nucleosomes to a level similar to mixed sequence DNA. However, the mechanism for the different effects of...
methylations and repeat number on nucleosome assembly is not clear.

### 3.3 Summary

The expanded CTG and CCG triplets were shown to generate nucleosomes with extremely unusual properties. We have demonstrated that DNAs containing 130 copies of CTG repeats assemble into nucleosomes with a stability nine times higher than any previously known natural DNA element. Moreover, expanded CCG repeats show nucleosome exclusion and methylation of the CCG repeats further enhances this exclusion, providing a possible molecular explanation for the basis of fragile sites in chromosomes. Finally, a DNA motif (CCGNN), based on the CCG repeat, excludes nucleosomes in vitro and is a DNase I hypersensitive site in yeast (unpublished data).

These findings provide us with a hypothesis in which expanded CTG and CCG triplets result in chromatin with unusual properties which can cause harmful biological effects including the generation of fragile sites and alteration of gene expression. Further, studies of the effect of these simple repeats in forming chromatin and, in the future, the ability of such templates to be replicated or transcribed will contribute greatly to our knowledge of the role of chromatin structure in fundamental biological processes.

### ACKNOWLEDGMENTS

I express my deepest appreciation to Dr Jack D. Griffith for his support. Most of the work described here was carried out in his laboratory.

| 8 In Situ Hybridization Electron Tomography | 31 |

Three-dimensional (3-D) structures at the molecular level of chromosomes and other cell structures are far beyond the reach of ordinary or confocal (3-D) light microscopy (LM). The electron tomography method (ETM), i.e. transmission electron microscopy (TEM) tomography, is able to provide methods of 3-D reconstruction of macromolecular assemblies, providing insights into the qualitative and quantitative spatial comprehension of macromolecular structures. ETM is a powerful method for developing reliable immunoelectron tomography (IET) and in situ hybridization analysis at the molecular level.

With ETM the data are collected with TEM by taking tilt series, i.e. projection images from different viewing angles over the object. By combining such projections taken over a sufficient angular range (from 0 to ±60° manually, e.g. in 3° increments), a wholly transparent 3-D representation of the object is recovered with necessary details. This requires the use of suitable computational methods.

Automatic single-axis tilt-series data registration is possible today that will not only allow the collection of data with increments as small as 1°, for high-resolution reconstructions of bulky whole mounts, but will also protect the specimen from electron beam damage (dose reduced by a factor of 10–100). Only automation of ETM procedures makes it possible to collect tilt series of cryo-electron microscopy (EM) preparations of unfixed and unstained preparations in vitrified ice, i.e. fully hydrated samples close to the native state.

Novel methods and tools for electron tomography are available that have been developed in different laboratories. Our electron tomography programs are automated to a high degree and therefore very fast and easy to use, in comparison with other program kits that are available. Specifically, our arsenal includes advanced tomography procedures based on the maximum entropy method (MEM) (e.g. 16-bit gray-scale MEM).

A collection of preparative methods for preserving whole-mounted chromosomes and cells for ETM studies has been developed. Examples of 3-D reconstructions of human chromosomes are shown at high resolution (3–15 nm).

It is considered that ETM allows 3-D reconstructions, depending on the thickness of the preparation, with a

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd
resolution in the range 2.5–8.5 nm. In this respect, some success was recently made as we were able to detect nanoprobes (1.4-nm immunogold markers) with the IET methods developed.

ETM of chromosomes involving localized genes with in situ hybridization and gold-labeling techniques is possible and would allow chromosome mapping in a 3-D configuration with molecular resolution much more accurately than any standard EM method which are affected by superimposing gold labels with their accompanying structures.

Concerning the structure and folding of the DNA in chromosomes, it is important to note that the linear sequence of bases in DNA is accompanied by higher level organizations, composed of loops, twists and folds in the long DNA chain, and, significantly, by DNA–protein interactions, e.g. nucleosomes, supranucleosomes, together with telomerase, topoisomerases and the new scaffold proteins [structural maintenance of proteins (SMC) family] recently described. These so-called 'higher order structures' are certainly very much involved in the regulation of gene expression in chromosomes. Further, it is easy to realize that genes distantly located in the linear sequence map could in fact be topologically associated when DNA is folded in chromosomes, and thus mutually regulated. Sequencing of the genomes does not include and cannot reveal higher order structures. It is only with ETM that genome maps can be brought in relation to 3-D molecular configurations, and it can be refined by combination with in situ hybridization to localize gene sequences and with IET to identify chromosomal proteins.

1 INTRODUCTION

1.1 Chromosome Structure

Higher order chromosome structure is an enigmatic and challenging problem. It is more than 100 years since the word chromosome first appeared in the literature, and almost 50 years since the principle of the DNA structure was established. The discovery of DNA structure was a turning point in biology and initiated the rapid development of molecular biology. We have been treated to detailed descriptions of various biological structures at the molecular level and various roles have been attributed to DNA. As for DNA, the overall principle of replication is clear, but many details even of replication have turned out to be uncompromisingly complex. In addition, the organization of DNA and the regulation of its function in interphase nuclei and its condensation into metaphase chromosomes at mitosis remain a distressing tangle in cell biology.

Difficulties in solving chromosome structure largely stem from the huge amount of DNA wrapped into chromosomes. Yet the packing and organization of the DNA in many phages and viruses with basically less DNA are also unclear. The length of DNA per diploid human somatic nuclei (diameter about 5–10 µm) is about 1.8 m. In mitosis twice as much is arranged into 46 chromosomes with a total length of about 200 µm. Consequently, the compaction proportion of the DNA in chromosomes is about 10^4:1.

In addition, the length and thickness of the chromosomes change dynamically when chromosomes condense in mitosis. Related changes are observed in meiosis, although the chromosomes are more attenuated and delicate, forming the so-called synaptonemal complexes when chromosomes pair up. In mitosis, early prophase chromosomes appear as long strands that reach full compression at metaphase. After mitosis, the chromosomes revert to their diffuse interphase form. In the interphase nucleus, chromosome positions tend to be conserved in their anaphase–telophase configurations. In this orientation, called the Rabl orientation, centromeres and telomeres occupy opposite regions of the nucleus. The chromosomes somehow rearrange themselves before the next division. Regions of interphase chromosomes, in yeast and Drosophila, have recently been shown to be in Brownian motion limited to a subvolume no more than 1% of the total nuclear volume of living cells.

What regulates, causes and lies behind the interphase chromosome movements and prophase contraction at the molecular level is not known, but such movements may be caused by proteins analogous to the contractile proteins of the cytoskeleton. Microtubules have not been observed, in higher eukaryotes, inside nuclei as long as the nuclear envelope (NE) remains intact. In lower eukaryotes, e.g. in yeast cells, bundles of microtubules are detected inside cell nucleus, at mitosis, as the NE remains intact in the budding. Bundles of striated microfilaments have been described in meiosis along the lateral elements of the synaptonemal complex (SC) and shown by immunological methods to react like actin, myosin and tubulin. The actual involvement in meiosis of these and many other immunologically indicated proteins is still controversial. It should be noted that the above-mentioned restricted Brownian motion of chromosome regions has been shown to be inhibited only by the microtubule-depolymerizing agent nocodazole and not by sodium azide, which is known to stop ATPase-driven processes.

In recent years, new groups of proteins have been isolated and shown to participate in chromosome contraction (the SMC family of proteins), sister chromatid cohesion apparatus (cohesin complex) and sister chromatid separation (separins that destroy cohesion).
In the folding of the chromosomes, different levels can be distinguished. Remarkably, there is a better understanding of how the DNA is organized in the chromosomes at the molecular level than at the gross chromosome level. This discrepancy may partly be due to the fact that chromosomes are too small for detailed studies at the LM level and too bulky for EM, that is, with conventional EM methods.

At the molecular level, an outstanding achievement was to reveal the association of DNA with histones to form particles called nucleosomes. The DNA molecule, the double helix itself, is 2.2 nm in diameter and makes a full helical turn of 3.4 nm (along the spiral axis) for each length of 10 nucleotide pairs of the double helix (10.6 pairs for free DNA and 10.2 pairs for nucleosomal DNA). (12) Almost two (1.75) full rounds of DNA totaling 2 × 83 nucleotide pairs are wound round the periphery of the nucleosome, which is roughly a cylinder 11 nm in diameter and 5.6 nm thick. It contains an octamer histone core, 6.6 nm in diameter and 5.6 nm thick, composed of two copies of each of the four histones H2A, H2B, H3 and H4. From the nucleosomes, now studied in crystallography down to a resolution of 2.8 Å, (12) polypeptide chains of the histones stick out. This is considered to play an important part in the regulation of the DNA–histone core assemblies (assembly vs disassembly), chiefly by acetylation and deacetylation of the histone tails. The DNA and histone cores are linked into a polyadenosome: an 11-nm thick ‘beads-on-a-string’ fiber. ‘Linker DNA’ of various length, from 0 to 80 nucleotide pairs, connects the nucleosomes. In this ‘beads-on-a-string’ association the DNA is packed lengthwise in a proportion of 6:1.

Chromatin, i.e. chromosome fibers, is biochemically a poorly defined entity varying with isolation sources and conditions and is composed of DNA with histones and chromosomal nonhistone proteins. The beaded-string organization is observed when chromatin is isolated and treated in buffers (pH 7.4) at low, i.e. hypotonic, salt concentration (10 mM), depleted of the divalent cations Mg2+ and Ca2+. (13) The required deficiency of divalent cations in the isolation procedures indicates that the rather loose beaded-string configuration cannot persist under physiological conditions. However, it is not known whether living cells are capable of regulating the concentration of the divalent cations intranuclearly.

In the presence of divalent cations, 1–5 mM Mg2+ or/and Ca2+, in neutral buffers, the isolated chromatin fibers observed have a diameter in the range 20–50 nm, depending on the isolation conditions. (13) The size is in better agreement with that of the chromatin and chromosome fibers observed in isolated whole mounts of, e.g. metaphase chromosomes. (13)

The prevalent concept of the folding of the DNA into the 30-nm chromatin fiber structure is likewise attributed only to histones. In this configuration the 11-nm polyadenosomal DNA fiber is anticipated to fold into a 30-nm solenoid with the incorporation of a molecule of histone H1 to each nucleosome. The binding site of H1 at the nucleosome has been defined but the arrangement of H1 in the 30-nm fiber organization is unclear. Recent data have positioned the globular domain of H1 close to the dyad axis, in a polar arrangement of H1 molecules along the nucleosome fiber that may influence gene regulation in addition to its structural role. (14)

The perplexity confronted in understanding the 30-nm chromatin or chromosome fiber structure is evident from various studies. (15) The observations have resulted in numerous models that can be roughly classified as (1) the original solenoid model, (2) some kind of a helical coil of the nucleosome fiber, (3) a beaded (superbead, supranucleosome, nucleomer) arrangement of the nucleosome subunits (16) and (4) a continuously variable zigzag nucleosomal ribbon. (4) The irregular zigzag nucleosomal ribbon has support from electron tomography studies, (4) cryo-electron tomography (17) and recently radiation experiments on chromatin in studies on living cells, (18) affirming linker lengths of 40 nucleotide pairs for an idealized zigzag model.

Estimating that 6–7 nucleosomes of the polynucleosomal string condense into one turn of a 30-nm thick chromatin fiber, the length of DNA is reduced in the proportion of 40:1. To obtain the 104:1 packing in metaphase chromosomes, further packing of 250:1 is required.

The prevalent opinion about packing the 30 nm chromosome fiber further into metaphase chromosomes holds that the fiber packs are packed into loops that are fixed to a chromosome scaffold structure composed of nonhistone proteins. (19) Topoisomerase II has been shown to be a main component of the scaffold proteins, making its contribution decisively important in sorting out tangled DNA strands after replication, in the condensing of chromatin loops and in the separation of the daughter chromosomes at mitosis. In addition, as mentioned above, certain new scaffold proteins have been shown to be involved in the condensation of chromosomes and in the separation of sister chromatids in mitosis. (20)

The chromosome scaffold was originally revealed in preparations of isolated metaphase chromosomes treated with high salt buffers (2 M NaCl solution) or dextran sulfate–heparin, to extract the histones and other soluble proteins. The extracted chromosomes were spread on a hypophase of a hypotonic solution. In these preparations clouds of looped dehistonized DNA could be observed surrounding a residual chromosome that principally persisted in the shape of the original metaphase chromosome. Only a residual chromosome scaffold remained after DNase digestion. With the same methods, an analogous nuclear matrix, nuclear skeleton
or cage of interphase nuclei was isolated, surrounded by clouds of looping dehistonized DNA, when digestion with nucleases was omitted.\(^\text{19}\)

These observations suggested a looped folding of the chromatin fibers around nonhistone chromosomal scaffold proteins\(^\text{19}\) as the principle of organizing the 30-nm chromatin fiber in chromosomes rather than a coiled-coil model. Consequently, the size, association and configuration of the regions [called scaffold-associated region (SAR) and matrix-associated region (MAR)] of looped DNA with the scaffolding proteins have been the object of various studies for the past decades, but contradictions and perplexities have hindered satisfactory concepts.\(^\text{19}\) For example, only a slight change in the conditions for the isolation of an interphase nuclear matrix\(^\text{19}\) resulted in a residual NE composed only of a nuclear pore complex (NPC) lamina fraction, depleted of an internal nuclear matrix. This may indicate the delicate and dynamic association of chromatin with the NE.\(^\text{18,21}\)

It is important to recognize the apparently different organization units of the different levels of chromosome organization: (1) the polynucleosomal DNA fiber, (2) the 30-nm chromatin fiber and (3) looping of the chromatin fiber somehow around the chromosome scaffold, forming the metaphase chromosome. In interphase nuclei, chromatin is organized around analogous structures, variously termed the nuclear matrix, scaffold or skeleton, which seem to be dynamically integrated with the NPC lamina of the NE.\(^\text{19,21,22}\)

Although the principal organization of the repeated building blocks at each organization level must be uniform, the variations and complexity in these repeats seem to increase from level to level. At the ‘beads-on-a-string’ level, the unit is the nucleosome with the linking DNA. For the 30-nm chromatin fiber the unit is 6–7 nucleosomes forming one turn, as assumed in the solenoid model, or their arrangement is more variable and flexible, namely an irregular nucleosomal ribbon according to the zigzag model or, as assumed in the supranucleosomal chromatin model, 7–42 nucleosomes are packed into various-sized 30–65-nm supranucleosomal units.\(^\text{23}\) At the next higher organization level the units are the loops bound by the scaffolding structures. The loop with an associated scaffold element seems to be the elementary building block towards higher chromosome organization. Variations of the loop sizes and the clustering of the loops into, e.g. rosette-like configurations have been observed and suggested in different instances.\(^\text{21,22}\)

How, then, do we understand the organization of the chromomeres?\(^\text{13,21,22}\) as described in the classical studies with LM? Chromomeres are best observed in prophase chromosomes of meiosis and they must in some way be folded by the 30-nm chromatin-loop organization with scaffold proteins.

Also, the bands seen in the giant polytene chromosomes of salivary glands in, e.g. Drosophila must in some way fit in, i.e. be a natural consequence of the folding of the 30-nm chromatin fiber. As polytene chromosomes represent tight lateral alignments of bundles of interphase chromosomes (up to 1024 chromosomes in Drosophila), the bands distinguished are considered to be apposed chromomeres\(^\text{13}\) of interphase chromosomes. Thus chromomeres seem to be organizational entities also in the interphase and not only consequences of early prophase chromosome condensation. This indicates that the folding of the 30-nm chromatin loops is actually preserved in interphase chromosomes, if we assume that polytene chromosomes are not distinctive exceptions. In addition, the size difference of the bands in polytene chromosomes must also be a natural consequence of an adequate chromosome model.\(^\text{21,22}\)

Chromosome coiling, i.e. the coiling of the chromonemata\(^\text{13}\) in classical descriptions from early LM studies,\(^\text{24}\) is another example of large-scale structural chromosome features that must fit with any presumed looping of the 30-nm chromatin with scaffolding proteins, if the model concerned is to be acceptable. In animal cells, chromosome coiling is not usually distinguished after ordinary treatment, i.e. without specific procedures.\(^\text{13}\) However, even without any specific treatments it is observed in plants with very large chromosomes (e.g. in Tradescantia), and also in living plant cells\(^\text{24}\) and in unfixed animal cells processed for EM.\(^\text{25}\)

Significantly, chromosome coiling also appears when ordinary chromosome preparations are squashed in 50%\(^\text{13}\) or isolated with 60% acetic acid (AA),\(^\text{22}\) indicating that chromosome preparations isolated with detergents under ‘physiological’ conditions or water spread\(^\text{13}\) somehow lose or disassemble the coiling. We can also presume that the banding technique that is used today in karyotyping might have the structural background in the underlying chromosome coiling, as has been suggested.\(^\text{26}\)

Immunological methods for staining topoisomerase II (a main scaffold protein) reveal a clearly spiraled internal core in chromosome preparations, similar to chromosome coiling.\(^\text{27}\) Also, 3-D reconstructions by electron tomography of chromosomes, after histone extraction and DNA digestion, appear as a coiled residual chromosome structure, indicating that chromosome coiling is maintained by scaffold proteins.\(^\text{28}\) Accordingly, in chromosome condensation, the coiling is somehow brought about in the folding of chromatin fibers by the scaffold proteins. It remains to be shown if scaffold proteins, when successfully isolated and dissolved, will self-assemble to coiled structures, especially when affiliated with DNA and histones.
Textbook diagrams and models for the higher order chromosome structure fail in giving substantial structural reasons for the several intermediate folding levels from the 30-nm chromatin fiber up to metaphase chromatids.\(^{(29)}\) Recent discussions,\(^{(30,31)}\) and earlier reviews of chromosome structure\(^{(22)}\) have tried to fill this gap. Having their particular merits, most chromosome models do not meet the criteria for an adequate and unifying model—those of comprehensively accounting for different-sized chromomeres of interphase chromosomes (e.g., polytene) and meiotic prophase chromosomes, for chromosome coiling and for the origin of

Figure 1 A unified model\(^{(10,21,22)}\) of higher-order DNA (DNA loop or chromatin fiber) folding in chromosomes: the loop-and-rosette model. The different categories of data (e.g., polytene chromosomes, Figure 2) fit best with this model. From interphase to metaphase chromosomes. (a) Single (histone-depleted) DNA loops and accumulations (duplications) of these in linear form, i.e., total or strictly local unfolding of chromomeres in a chromatid. (b) Arrangement of various size classes and organization types of chromomeres in a partly stretched-out interphase chromatid. The folding of a continuous DNA by looping: single loops which would correspond to primary replicons; double loops, multiple loops and rosettes (around ring-like cores of scaffold elements, i.e., cyclomeres\(^{(8)}\)) and their clustering; representing the origins for different-sized chromomeres during evolution. (c) The condensed form representing the metaphase chromosome. Ring-like structures are embedded in the chromatin. Note the similarity of appearance in a section of the premeiotic X chromosome of Acheta, (d), and in a stereo pair critical-point drying (CPD)-whole mount of a Chinese hamster ovary (CHO) metaphase chromosome (prepared as in section 2.4, Procedure: 1b) shown in (e). There is a complete analogy with a chromatid of the polytene chromosome. Only the condensation is different as no lateral apposition of chromatids occurs. Instead, a linear apposition causes chromatid coiling and linear condensation of the chromosome arms. This would be chiefly due, not to the condensation of interchromomeric DNA, but rather to the tendency of the chromomeric core elements (scaffold elements, i.e., cyclomeres and their subunits) to interact and assemble. Proteins of these interactions have recently been identified as the SMC family among scaffold proteins.\(^{(10,20)}\) This results in higher-order structures such as chromosome (chromatid) coils, in which chromomeres are arranged in analogy with nucleosomes in the models of 30 nm chromatin fiber, either as in the solenoid model\(^{(15)}\) or as in the zigzag nucleosomal ribbon model.\(^{(4)}\) (f) 3-D reconstruction of the chromosome shown in (e), from tilt series with 6° increments (section 4.2), with MEM (section 5.4), visualized with BOB (section 6.1), shown in stereo pairs (recorded with SNAPSHOT from Silicon Graphics Inc. (SGI) display). (g) Stereo views, with 10° increments, of the reconstructed chromosome in (f). Note that chromosome coiling is recognizable as chromosome banding and the impression of bands depends also on the viewing angle. (h) Stereo series as in (g). Details of the chromosome arms with coiling (arrowhead) and ring-like structures of cyclomere size (arrows), surrounded with looping fibers of hazy chromatin. Note that these fibers are not detected in the chromosome scaffold, Figure 8(a, e) (cf. the MEM/3-D reconstruction of chromosome scaffold Figure 8a, b, e). (Reproduced from Engelhardt.\(^{(22)}\))
and interplay with the chromosome scaffold and nuclear matrix.

It is worth noting that, when the chromosome material (chromatin) coils and (therefore) compacts, the two levels of coiling, (1) the 11-nm fiber to the 30-nm fiber and (2) the extended chromonema to the compacted mitotic chromosome or chromatid, appear closely similar and suggest analogous configurations of condensation (solenoid and zigzag configuration, see the notes in the legend of chromosome model, Figure 1).

Our early investigation of chromosome structure, with a unifying intent, started partly from theoretical postulates that motivated a search for adequate fixing and staining methods with ruthenium red (RR) (developed for intracellular staining, see section 3.5) for meiotic chromosomes in order to reveal details in the attachment of DNA to the NE and to the SC. The methods revealed the distinct presence of ring-like cores (which we named cyclomeres) in the premeiotic X chromosome of Acheta and also along the lateral elements of the SC. The ring-like
Figure 1 (Continued)
Figure 2 The loop-and-rosette model from interphase to polytene chromosomes. (a) As Figure 1. (b) As Figure 1. (c) As (b), showing that the small DNA loops (1.2–2.2 kb) as seen in polytene chromosomes,⁴¹,²² are bound by 6–11 nucleosomes that form superbeads (30–60 nm in diameter, cf. metaphase chromosome, Figure 7), because of the short loop lengths associated with the scaffold elements. (d) Polytendisation: lateral apposition of chromatids (only four chromatids are drawn for clarity to show the principle), demonstrating the formation of the bands of different thickness. A constriction is interpreted as tendency for primary chromomeres (single loops) to fuse from separate chromatids, rather than as point of underreplication as has been formerly suggested (references in Engelhardt⁴²). (e) General view of a whole mount of a CPD polytene chromosome (prepared as the metaphase chromosome in Figure 1e). (f) Stereo pairs of details at higher magnification. Ring-like structures (thin arrows) can be seen. In some rings (encircled) granular subunits are detected. (g) Ring-like alignments of scaffold-forming subunits (circles containing thin arrows) can be visualized in the bands, and they are similar to those found in metaphase chromosomes (cf. Figure 1e–h). This indicates that polytene chromosome bands are composed of the same scaffolding ring-like structures and subunits as metaphase chromosomes and this is best shown when the gross structure of the bands is also well preserved. (Reproduced from Engelhardt.⁴²)

structures could be traced to derivatives originating from the NE. More specifically, the structures appeared to be virtually identical with an apparently detachable nuclear part of the bipartite NPC. Striated microfilaments lining the lateral elements of the SC were revealed. Apparently, they connect neighboring cyclomeres and may represent the NE lamina. Certain lamina proteins have indeed recently been shown by immunoelectron microscopy (IEM) after DNase digestion to be present throughout the nuclear interior.³²

It was suggested⁸ that the DNA is folded around these ring-like cores, which function as the control elements for replication and transcription. The folding of DNA around these foci emerged as the most convenient way of packing DNA in interphase and metaphase chromosomes. The DNA folding (Figure 1) was presented as the loop-and-rosette model.²² This implied a natural reason for the different sizes of chromomeres as arising naturally from replicon duplication and from the clustering of repeated replicons to rosettes. By the same principle, a model for polytene chromosomes was presented (Figure 2).²¹,²² The details and consequences have been extensively discussed²² in relation to the NE, chromosome scaffold and the nuclear matrix, and as resulting in the evolution of the chromosome structure.

This integrative model, in retrospect, involved details that strikingly resemble present-day concepts about the central control of replication machinery of eukaryotes. This machinery, with its rosette-like control elements, appears to be uniform from yeast to higher eukaryotes,⁴,³³ and the proposal of eukaryotic chromomeres as replication and transcription factories, also composed of rosette-form configurations, has been presented.³¹ The protein composition of the replication foci involves different dynamically associated proteins, now identified.³³ A single (170-kDa) structural protein, called foci-forming activity (FFA-1), assembles as a ring-like core of the foci that generate the loop replicons. It is a novel protein according to limited sequence data.³³ It
remains to be seen if these proteins have any relationship with our early suggestions. (8)

1.2 Electron Tomography Compared with Earlier Methods

The theoretical resolution of TEM at 100 kV is 0.003 nm, which is sufficient for visualizing atoms (the van der Waals radius of the hydrogen atom being 0.12 nm and that of carbon 0.2 nm). In practice, owing to instrumental constraints and other restrictions that are difficult to overcome, (54) the resolution for modern TEM is at best 0.1 nm, which is still of the magnitude of atomic resolution accomplished, e.g. in TEM crystallography. (35) However, in biological samples the practical resolving power is often not better than about 1–2 nm. At least partly, this is in practice because details in images are in variable degrees superimposed owing to specimen thickness.

Inspection of stereo pairs greatly improves the actual resolution of structures under study, because it eliminates the superimposition of structures. This is accomplished with a mirror stereoscope (e.g. Old Delft, with auxiliary 4.5 × magnification) viewing photographic negatives in transmitted light. This technique has been found most useful and advantageous for interpreting bulky whole-mounted chromosome preparations after, e.g. digestion and treatment procedures. (22)

However, the modern 3-D approach is the ETM, i.e. TEM tomography, (36) to replace the static 3-D viewing of stereo pairs. TEM produces images that are orthogonal projections of the 3-D object under study. Tilt series of image projections of an object from 0 to ±60°, with e.g. a 3° increment, are recovered with a eucentric goniometer specimen holder that is usually incorporated in a modern TEM instrument. The set of projections in tomography are named Radon transforms after Radon (1917), who first presented the mathematical (back-projection) method of rebuilding the original 3-D object from its projections. (36) It was only in 1968 that such an approach was put forward for 3-D reconstruction in TEM studies of biological samples, (37–39) authored in three independent papers. (40) At present ETM allows reproducible 3-D reconstructions with a resolution of 2.5–8.5 nm. (41)

Only in recent decades has ETM become a useful tool in structural biology (36,42) because of the great increase in computer power available. Chromosome studies have played a pivotal role in the development of ETM as described in a detailed review by Woodcock, (4) who also mentions that the MEM in ETM was first used in chromatin studies. (43) One of the first successful tomographic reconstructions of a whole-mounted chromosome (spread on water surface), (44) attempting to track the folding of the chromatin fiber, was performed by a filtered back-projection method with an ‘exact’ filter algorithm.

The reasons why ETM has not yet become a widely used tool in structural biology were discussed at a recent meeting. (46) Earlier methods have been time-consuming in the extreme. It could take weeks or months to collect the amount of data that the present digital technology provides in days or hours. In addition, as the research community engaged in developing the methods has been rather small, the number of high-impact papers showing striking and convincing results is still relatively small. All this may soon change as programs, high-performance computing and instruments become available.

With the lack of efficient methods, biology has been working in a relatively flat world in trying to understand structures and functions at the molecular level. Yet these things occur in a dynamic 3-D environment. It is with ETM that we are beginning to have a closer look at this 3-D cell environment. In particular, there is at last a solid prospect of comprehending, with ETM combined with immunological, (47) in situ hybridization and with other methods, the higher order structure of chromosomes, the intricacies of which – as presented by the mingled 3-D hierarchy, the manifold of scaffold proteins, (10,11,19) and the DNA folding enigmatically connected with all this – have so far been next to impenetrable.

2 PREPARATION STEPS FOR CHROMOSOMES

2.1 General

As previously discussed, (4) there is in fact no consensus on how to prepare chromosomes for ETM investigation. In addition, ordinary EM fixation methods for, e.g. thin section studies are insufficient for revealing details in nuclear and chromosome configuration, as recognized earlier. (8) To show details of nuclei in sectioned material, staining and preservation with, e.g. various RR methods, as mentioned above, have proved to be more revealing. (8) Viruses with known surface decoration are useful as test objects for developing fixation and preservation methods for ETM. (28) Viruses can also be used as internal standards in situ hybridization and with other methods, which – as presented by the mingled 3-D hierarchy, the manifold of scaffold proteins, (10,11,19) and the DNA folding enigmatically connected with all this – have so far been next to impenetrable.
Reconstruction from sections of epoxy resin embeddings that are commonly used in EM may not be the best method. Sections, however, may often be the only choice to select an embedded specific object for reconstruction, e.g. chromosomes from certain tissue samples, cell aggregates or cultures. According to our experience, reconstructions obtained from sections are not usually as successful as those from whole mounts. The reason might be that sections suffer from various kinds of deformation that are not easily controlled, e.g. in cutting sections with the ultramicrotome and picking them on the grids, in addition to the observed thinning, up to 50%, of sections in EM, in the collection of tilt series. (4) Also, the signal-to-noise ratio is degraded in embeddings. Noise is a general problem also in cryo-TEM when unstained specimens are embedded in vitreous ice. However, the low signal-to-noise ratio may significantly be improved by removing the epoxy resin (or other embedding medium) from sections, thus making a kind of whole-mount preparation of these sections (section 3.5).

Whole mounts of, e.g. chromosomes are preferable for achieving a high signal-to-noise ratio and to secure that the whole content of the object under investigation is carried along. This is not always the situation for ultrathin sections. Sections of large organelles such as eukaryotic chromosomes and nuclei can, however, be of advantage when specimens such as whole mounts are too thick for ordinary 100–120-kV TEM; in earlier studies it was considered that 1 MV was the only choice for chromosomes. (13) For instance. Today, with modifications of preparative methods, 100–120-kV EM has proved sufficient for whole mounts, not only for whole-mounted chromosomes, but also various parts of whole-mounted cells. (47)

2.2 Chromosome Isolation and Whole Mounts

It is sufficient to present the main principles used in chromosome isolation methods because details of the various procedures developed over the years have been published and thoroughly reviewed earlier. (48,49) This equally applies to chromosome scaffold isolation, (19) where new chromosome isolation methods have been introduced.

If a high yield of chromosomes is required, chromosomes are isolated in bulk from synchronized cell cultures (49) of established cell lines that are used in cytological laboratories, e.g. HeLa (human) and CHO cells.

The procedure is as follows. Cell cultures in logarithmic growth phase, when the confluence of cells is 50–60%, are synchronized with the addition of (2 mM) thymidine in the cultivation medium and incubated for 16–22 h (depending on the cell cycle for cell lines used). The growth medium, with thymidine, is replaced with a fresh medium including a mitotic inhibitor, e.g. (0.06–0.1 μg mL⁻¹) Colcemid (nocodazole or vinblastine for certain cell lines), with more (10–20%) than ordinary (5%) calf serum, or fetal calf serum, and incubated for 8–12 h. Cells in mitosis are released, naturally or aided by gentle shaking, into the growth medium, because in the cell lines to be used (e.g. HeLa, CHO) mitotic cells are rounded up and detach from the bottle surface. Mitotic cells are collected from the medium by centrifugation.

It is generally essential for a successful isolation of metaphase chromosomes with most of the chromosome isolation methods used that mitotic cells are swollen by hypotony by dispersing the pellet of mitotic cells in a hypotonic solution, e.g. 75 mM KCl, for about 10 min, at room temperature (RT) or at 37 °C. Some cells need first to be washed with the hypotony solution to make the hypotony treatment effective. The swollen cells are then collected gently by centrifugation, e.g. at 800–1000 rpm for 5–10 min. The total treatment time, including the centrifugation, must not exceed 15 min. This is important when divalent cations (Mg²⁺ and Ca²⁺) or polyamines, that are essential for chromosome stabilization, are not present (but see Mendelsohn, (49) with divalent cations present).

After the hypotony treatment, any of the various chromosome isolation procedures, (19,46,49) e.g. physiological or less physiological, are convenient.

The only general requirement for isolating chromosomes and nuclei and keeping them stable, with e.g. 5–10 mM (or lower) N-(2-hydroxyethyl)piperazine-N'-(2-ethanesulfonic acid) (HEPES) buffer at pH 7.4, appears to be the presence of divalent cations (1–5 mM Ca²⁺ and/or Mg²⁺) or polycations such as spermine (0.0125 mM) and spermidine (0.05 mM). (27) Monovalent salts only tend to cause aggregation.

Mitotic cells are also suited for the microspreading methods of mitotic (50) or meiotic chromosomes, (51) either without or with hypotony treatment.

The procedure is briefly as follows. In this method the cells are spread on water, or on hypotonic salt solution for more gentle spreading (0.05–0.1 M NaCl), to control better the spreading forces at the hypophase that break the cells and release the chromosomes. The chromosomes are picked from the hypophase surface on poly-L-lysine (PL) (below) or glow-discharged (51) carbon–Formvar-coated grids, after dehydration in methanol (MeOH), lightly stained with (0.001–0.002%) uranyl acetate (UA) in MeOH (30 s), washed in MeOH and dried by CPD (section 3.1).

With this elegant method, the chromosome preparations are ready for EM, without laborious purification and isolation procedures. There is the disadvantage that cytoplasmic obscuring components may also attach on the grid preparations. It is for the investigator to choose...
the chromosomes on the grids, which does not seem to be too difficult a procedure as we can see in, e.g. DuPraw’s splendid pictures of spread chromosomes.\(^5\)

From the viewpoint of early chromosome morphology, these isolation methods yield the unexpected result that chromosome coiling is indistinct after any of the ‘physiological’ isolation or spreading methods, especially at neutral pH. The reason for this is not clearly understood.\(^1^{13}\) Chromosomes squashed in 50% AA\(^1^{13}\) after standard cytological fixation in MeOH–AA (3 : 1) do show distinct coiling.

Chromosomes isolated in bulk in 60% AA, after hypotony treatment, surprisingly show the same chromosome coiling\(^2^{22}\) when the loose pellet of swollen cells is washed and dispersed in 60% AA. This method works also for cells that have been fixed, and stored at \(-20^\circ\)C, in MeOH–AA (3 : 1). The pellet of chromosomes, after centrifugation (1500–5000 rpm, 10–15 min), may appear indistinct depending on the initial amount of cells used. In any case, the pellet is washed in 60% AA, two or more times, and collected by centrifugation. After washing in 60% AA the chromosomes are diluted in a small amount of 60% AA and stored at +4 or \(-20^\circ\)C. After this procedure, a suspension of pure chromosomes, with 10–30% prophase and interphase nuclei, is found, with insignificant amount of cytoplasmic debris, when investigated by phase-contrast microscopy. Distinct chromosome coiling is visible with phase-contrast microscopy. The chromosomes do not aggregate when pelleted by centrifugation and the pellet is easily redispersed.

Polytene chromosomes can also be isolated by this method but to release them from nuclei they have to be spread on, e.g. 60% AA.\(^2^{22}\) The chromosomes are then picked on polystyrene-coated grids (below), dehydrated, lightly stained with UA (above) and CPD (section 3.1) or tert-butanol dried (section 3.2).

In the AA-isolated metaphase chromosomes, the clearly preserved coiling matches classical chromosome descriptions. Thus, the AA-isolated chromosomes seem to be tempting objects to use to study the higher order chromosome structure related to chromosome coiling.

The metaphase chromosomes are mounted on EM grids by centrifugation (1–5 min, 500–1500 g) of a sample (5–10 µl of diluted chromosome solution, or 2–3 µl of the loose pellet) through a cushion of 60% AA, in microchambers (Figure 3) for grids (50–200 µl).

The centrifugation for mounting chromosomes on the grid is preferred as chromosomes are better preserved in their 3-D configuration than with other more direct application methods.

With AA, Formvar or carbon–Formvar-coated grids are not suitable, as they are not resistant to AA. However, grids coated with plastic (polystyrene) films (Petri dish pieces, e.g. Nunc, Nalge Nunc Inc., dissolved to make

\[ \text{Figure 3} \] Grid microchambers are made of plastic hematocrit tubes (1). The plug (2) of the tube is cut off (arrow) so that the plug can be easily forced to the required depth (arrowhead), into the cut-off top part (3) of the hematocrit tube to function as the bottom for the grid. Chambers of suitable sizes are thus easily obtained, e.g. 50–200 µL. The caps of a 0.5 mL micro-centrifuge (Eppendorf) tubes (4) are used as adapters for (3) fitted to 0.5 mL micro-centrifuge (Eppendorf) tubes (5) (which fit into a larger tube for a swing-out desktop centrifuge, not shown). When a swing-out desktop centrifuge is not available, the 0.5 mL cap is positioned in a 45° angle (white arrow) in a 1.5 mL micro-centrifuge (Eppendorf) tube (6) with a u-form cut (white arrowhead) for the grid microchambers (7), as a substitute in a swing-out position to have the sample evenly distributed over the grid. If high centrifugation speeds (over 1500 rpm) are used, the caps at 45° angle must be fixed (glued or melted) to be kept in place. These chambers are analogous to Miller’s grid chambers\(^5^{31}\) but faster and easier to make.

A 0.5% solution in 1,2-dichloroethane, without or with additional carbon coating, are resistant to AA.\(^2^{22}\) These films are stronger than Formvar films but less adhesive. To prevent the film peeling off the grids, the latter may first be treated with an adhesive solution (0.01% polystyrene in benzene).\(^5^{51}\)

Before mounting chromosomes on the grids, fiducial gold markers that are needed for the alignment of the images of the tilt series for ETM are applied on the grids. Ni or Au grids are preferable as in the presence of gold Cu will wither when stored. Colloidal gold markers are applied by dipping the grid, one or both sides, in a drop of, e.g. 5-, 10-, 15- or 40-nm colloidal gold solution diluted to, e.g. 1 : 10, with filtered double-distilled water (FddH\(_2\)O) (0.22 µm filter, Millipore) or with PL, e.g. 0.01–0.1 mg mL\(^{-1}\) in FddH\(_2\)O. Being uniformly more round and less liable to aggregate, commercial immunogold particles (e.g. expired) are more advisable than self-made particles. The grid, with adhering gold suspension, is immersed in 100% MeOH that precipitates the gold on the grid. This procedure is repeated, if
necessary, to obtain the amount of gold needed. The minimum number of gold markers is three [or four], preferably 8–12 or more, for the image area and the magnification used. The same gold particles must be identified on each image in a tilt series (from 0 to ±60°, e.g. in 3° increments). The size of gold particles chosen depends on the magnification that will be used for the reconstruction. In addition, a mixture of different-sized gold particles is useful for different magnifications. With PL, the dilution of the gold suspension may be increased to a much higher degree. However, we observed the drawback that when embedded in PL, the gold markers look less sharp and are difficult to distinguish, especially at high tilts.

2.3 Pretreatments: Salt Extraction and Enzyme Digestions

When the chromosomes are mounted on grids, they are ready for further procedures for EM. If salt treatments or enzyme digestions are required, they must be completed at this stage, before postfixation and staining are performed.

Note that the methods that follow are suited also for other than AA-employing chromosome isolation methods and for microspreading methods. The point is that the chromosomes are attached on grids for easy transfer to different solutions used.

The attachment of isolated chromosomes with centrifugation, in the isolation buffer used, is secured by treating the carbon- and film-coated grids with, e.g. PL (0.1–1 mg mL−1 in FddH2O), for about 1–5 min, followed by washing in drops of FddH2O. Also, glow discharging makes the carbon or plastic film coating hydrophilic and contributes to attaching chromosomes on the grid surface. The same effect is obtained by UV radiation (10–30 min) or dipping in alcohol followed by air drying (AD).

These procedures are not necessary with AA-isolated chromosomes, as they do stick on hydrophobic polystyrene film-coated grids with carbon or not. Also, PL does not harm the attachment of AA isolated chromosomes.

To remove the grid easily from the microchambers after centrifugation, follow a simple procedure. After centrifugation, add 60% AA to form a convex surface in the micro-chamber. Retrieve with curved anticapillary (and antimagnetic, for Ni grids) forceps by flipping the chamber upside down to let the grid float on the surface of the hanging drop. If the grid does not detach from the bottom by slightly rocking the microchamber, it can be released by touching with a thin needle or one arm of the thin forceps on the periphery of the grid.

Grid washings, etc. are accomplished in, e.g. a large Petri dish, with moistened filter-paper, overlaid with Parafilm. The Parafilm is preferably provided with drop-sized depressions (Figure 4).

The grids are washed in HM (10 mM HEPES, pH 7.4, 5 mM MgCl2) or HC (10 mM HEPES, pH 7.4, 5 mM CaCl2) buffer on the Parafilm, with several droplets (1–5 min in each) to remove the AA and to balance the pH to neutral. AA-isolated chromosomes retain their morphology when transferred to water solutions containing divalent cations at neutral pH. (For a routine, it is recommended to use double-distilled water, and filter (0.22 µm, e.g. Millipore) all solutions. Also use rubber gloves, wash if powdered.)

To isolate the chromosome scaffold, histones are extracted with, e.g. 2 M NaCl solution and digested with DNase and RNase.

However, chromosomes isolated with 60% AA, according to our sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS/PAGE) analysis and immunoblotting, show no or negligible amounts of histones, the bulk of which appears in the primary 60% AA extract.

Thus extraction with 2 M NaCl-solution apparently is not necessary to extract histones. In any case, digestion with DNase I (10 µg mL−1) (Boehringer), with or without RNase A (10 µg) (Boehringer), completed in 2 M NaCl in HM buffer, shows better results when monitored with DNA-specific fluorochromes, e.g. DAPI (4',6-diamidino-2-phenylindole) (Sigma), 0.25–0.5 µg mL−1, in the digestion solution.

Figure 4 Depressions on Parafilm are obtained as follows. Take two incubation chambers with 96 wells, one with round-bottomed wells, frames removed. After inserting Parafilm (with its cover paper, not shown) between the two chambers, press together. The ‘dimples’ formed will ensure that the incubation drops (about 50 µL) do not float around during washing steps, when positioned in a large petri dish with moistened filter paper (to prevent the drops from drying during incubation).
After DNase I digestion in 2 M salt–HM buffer for 1–2 h at RT, no DNA-specific fluorescence can be detected after washings in 2 M salt–HM buffer followed by washings in HM buffer, and mounted in DAPI mounting medium (MM) (90% glycerine, 0.25–0.5 µg mL⁻¹ DAPI, in HM or HC, with antifading substances such as 10–20 mM dithiothreitol or 2-mercaptoethanol). Many commercial antifade/bleaching embedding products are available (note that the presence of divalent cations is necessary for the stability of isolated chromosomes).

Any other enzyme digestions desired are performed similarly [cf. hyaluronidase⁴¹,⁴²], sequentially or if possible simultaneously, in the buffer solutions required.

Control preparations are made in the same salt buffers but without the enzyme, denatured enzymes or with enzyme inhibitors.

For enzyme digestion of resinless thick sections of whole-mounted cells, see section 3.5.

### 2.4 Fixation of Chromosomes

Chromosome preparations, with or without various pretreatments, preferably are chemically postfixed with glutaraldehyde (GA), a cross-linking substance and a reliable preserver of cellular ultrastructural details. Our purpose is to maintain the chromosome coiling for 3-D reconstruction. AA is not a cross-linking fixative but preserves the higher order chromosome structure, e.g. chromosome coiling, by acting as a precipitator of chromosomal nonhistone proteins. As mentioned, there is no consensus on how to preserve chromosomes for ETM,⁴ so the field is open to the development of new fixation methods for testing and refining. Cautious fixation and staining are important especially after digestion–extraction steps when the residual delicate material left might easily be lost in washing steps or the configuration might change during dehydration steps before, e.g. CPD (section 3).

We have found it advantageous to use a set of various fixation procedures as a standard protocol to test different constituents and their combinations on the 3-D structural preservation and appearance. This concerns not only methods for structural chromosome studies but also any other material such as whole-mounted cells, e.g. in developing IET⁴⁵ methods (section 7).

Fixing and preserving whole mounts is a delicate procedure, as too much contrast, i.e. electron density, must be avoided to keep specimens transparent, when conventional 100–120-kV TEM is used for collecting the tilt series. The methods used in standard thin-sectioning studies, where high contrast is rarely a problem, will not work well if not modified. Little attention has been paid to developing preparative methods for whole mounts for TEM. The quality of ETM 3-D reconstructions depends as much on the development of programming methods and the performance of TEM as on the development of specimen preparative techniques suited for ETM, just as early EM depended on the instrument but equally on developing specimen preparative techniques.

CPD and other 3-D preserving methods (section 3) are used to avoid drying artifacts after the fixation procedures. It has been reported,⁵⁵ however, in scanning electron microscopy studies, that GA shrinks cells to some 45%, despite CPD. The shrinking by GA was prevented by using tannic acid (TA), after osmium tetraoxide (OT) fixation.

We tested the TA procedure using viruses as test objects. We had previously found that viruses fixed with GA appeared slightly smaller than recorded in the literature, after drying from solidified tert-butanol (analogous to CPD, section 3.2) for 3-D reconstructions by ETM.⁵⁸ With TA included in the fixation procedures, the size of the viruses appeared more in accordance with the reported sizes of the viruses (unpublished work).

Upon testing the TA method on chromosomes, the chromosome fibers appeared significantly thicker (40–60 nm) than chromatin fibers without TA (35–40 nm). In addition, the chromosome fibers appeared to be composed of supranucleosome-like particles of various sizes rather than a more regular fiber that the solenoid model predicts (cf. Figures 5 and 6 with Figure 7). In addition, the organization of the chromosome scaffold fibers changed appearance with TA.⁵⁴

In our present standard fixation protocol, TA is included with GA, OT and UA with some modification of the original method.⁵⁵ Fixation controls, to test the effect of the different substances and their combinations, are used.

Dehydration and staining with UA (0.001–0.002%) in MeOH are performed in microcentrifuge tubes (Eppendorf) (1.5-mL test tubes). Curved anticapillary (and antimagnetic, for Ni grids) forceps are advantageous in the transferring steps.

The procedures are as follows. The fixation and preserving methods, for AA-isolated chromosomes and chromosome scaffolds, are accomplished with chromosomes mounted on grids:

1. (a) No postfixation;
   (b) boiling in 50% AA, for 30–60 s;
   (c) wash, 3–5 x, in HM or HC buffer, if the specimens are brought to salt and enzyme treatments, section 2.3;
   (d) dehydration (30, 50, 75, 100%, 10–30 s per step) in MeOH;
Figure 5  (a) Example of a low-resolution 3-D reconstruction with weighted back-projection method (WBM) of AA-isolated (HeLa) metaphase chromosome (prepared as in section 2.4, Procedure 1(b), and dried from tert-butanol, section 3.2), visualized with BOB (section 6.1; Figure 1f). The WBM has been low-pass filtered to 25 nm. Chromosome fibers of 25–60 nm are seen. Streaks seen in depth direction are artifacts that appear with WBM due to the missing data and other discrepancies (e.g. alignment inexactness, when tilting parameters are not accurately determined, especially with the angle of tilt axis being manually approximated, produces whirl-like streaks, arrow, in the reconstruction). [Reproduced by permission of the Center of Scientific Computing from Engelhardt et al.\textsuperscript{28} and also from Engelhardt and Ruokolainen.\textsuperscript{54}] This case of ETM, scanning, alignment and WBM was processed with the programs developed in Dr U. Skoglund’s laboratory, Department of Cell and Molecular Biology, Karolinska Institute, Stockholm, Sweden, in 1993. (b) Details, in stereo pair of (a), at higher magnification. Chromosome fibers (20–60 nm) appear smoothed (low-pass filtered) with no sub-details detectable.

(e) staining in (0.001–0.002%) UA in MeOH for 30 s, wash in MeOH (3×);

(f) drying, with 3-D preservation methods, e.g. CPD (section 5);

Comment: boiling in 50% AA\textsuperscript{22} causes additional purification of chromosomes from histones and cytoplasmic fragments.

2. Rapid TA method for chromosomes, modified from:\textsuperscript{55}

- washing in HM buffer (3–5×);
- fixing, for 2–5 min, in mixture (1 : 1) of:
  - 1% GA in HM buffer, pH 7.4;
  - 0.5% OT in 0.1 M sodium cacodylate (NC) buffer, pH 7.4;
- washing in HM buffer (3–5×, 0.5–5 min);
- 0.5% TA in 0.1 M NC/HM buffer (1 : 1), 5 min;
- washing in HM buffer (3–5×, 0.5–5 min);

(a) staining with (0.001–0.01%) UA in FddH\textsubscript{2}O, 5–10 min;
(b) without UA in FddH\textsubscript{2}O:

- dehydration, staining in UA in MeOH, and drying as in (a).
Figure 6 (a) Chromosome (HeLa), prepared as in Figure 5, showing 3-D reconstruction with MEM (section 5.4) of a chromosome telomere, in stereo (see above). (The original magnification of the tilt series was 48000×, scanning pixel size 20µm, giving the original resolution as 0.42 nm. With 6 × binning, the voxel size is 2.5 nm for the volume, i.e. the ‘conservative estimate’ of resolution is not better than about (2–4) × 2.5 nm = 5–10 nm.) Some details (cf. Figure 5a) of chromosome fibers may be detected even at this low magnification. (b) At high resolution, the chromosome fibers appear decorated with details, but are difficult to interpret. Histones are extracted by AA but DNA is present (cf. immunoblotting analysis of histones and DNA fluorescence with DAPI in Figure 8d). [Reproduced from Engelhardt and Ruokolainen.]

Controls and modifications:
3. as in 2, but without TA;
4. as in 2, but without OT;
5. as in 4, but without TA;
6. as in 3, but without UA.

3 PRESERVATION METHODS FOR THREE-DIMENSIONAL RECONSTRUCTIONS

3.1 Critical-point Drying

After fixation, the whole-mounted preparations have to be dried. AD causes artifacts, shrinkage, wrinkling and distortion that destroy the 3-D configuration. Drying artifacts are caused by disruptive effects of the surface tension of the fluid from which they are dried, e.g. water but also substances such as alcohol, used for dehydration, have a surface tension high enough to destroy delicate 3-D configurations.

The problem was recognized and solved in the early development (1950) of TEM techniques by T.F. Anderson, who introduced the CPD method. CPD is conventionally used for whole-mount studies with scanning electron microscopy. CPD needs, however, an apparatus where the procedures are performed at high pressure.

CPD can be briefly described as follows. After the grid samples have been gradually dehydrated in steps, e.g. in MeOH, the grids are put in a grid holder in the CPD apparatus, with some dehydration fluid, and the MeOH is completely replaced with liquid carbon dioxide (CO₂), at a high pressure (60–65 atm) in several (7–10) washing steps with liquid CO₂. CPD is completed, at an elevated pressure of about 100 atm (Pₛ = 73.8 bar), by increasing the temperature to ca. 40 °C. Keeping the temperature above the critical point temperature (Tₛ = 31 °C), the pressure is slowly decreased, regulated by a relief valve. After CPD, the specimens are ready for TEM.

However, CPD has some disadvantages such as causing thermal and pressure stresses in the specimens that may be difficult to avoid. An apparatus is needed for the procedure that may not always be available. The procedure needs liquid CO₂, preferably dried to remove
Figure 7 Chromosome (AA-isolated from HeLa cells), pretreated with TA before CPD to avoid shrinkage (section 2.4, procedure 2): (a) original tilt series at 0° tilt [reproduced from Engelhardt and Ruokolainen54] and (b) +60° tilt with mean diameter of the 30 nm chromatin fibers (arrow) increased to 30–60 nm with globular domains 30–60 nm in diameter. (c) Stereo pair of 3-D reconstruction with MEM (section 5.4) of the chromosome fiber [shown in (a) and (b) with an arrow]. The 30–60 globular domains of the chromosome fibers appear decorated and seem to be connected by two (2–4-nm) thin strands. [Reproduced from Engelhardt and Ruokolainen.54]

minute amounts of water that may be present.56 The water present in liquid CO2 was shown56 to be the reason for drying artifacts such as thickening of cytoskeleton fibers in the microtrabecular lattice.57 In addition, the CPD procedure takes time to finish.

3.2 Drying from tert-Butanol

When an apparatus for CPD is not available, a substitute for CPD is drying of the grid samples infused with tert-butanol. This method needs no expensive accessory, although such an apparatus has been constructed.58 The procedure is much faster than CPD and is claimed to give analogous results. The method is easy to accomplish, with only a few restrictions, as ordinary grids coated with Formvar are not resistant to tert-butanol. However, plastic films (section 2.2) that are resistant to 60% AA used in chromosome isolation with an AA procedure are suitable for tert-butanol drying. In addition, grids with a pure carbon film coating are usable.

After the dehydration steps with, e.g. MeOH (and staining with UA in MeOH) of the grid samples, microcentrifuge tubes (Eppendorf) (1.5 mL) are used: one tube with a mixture of MeOH–tert-butanol (1:1), and then a series of 3–4 tubes with 100% tert-butanol (tert-butanol is liquid at temperatures above 25.5 °C). The grids are washed in each step for 10–60 s. After the last step each grid is dropped to the bottom in a separate microcentrifuge tube (Eppendorf) (1.5 mL) with about 0.5 mL of tert-butanol until all grids are ready. After infiltration with tert-butanol, the fluid is changed several times, if considered necessary, by gently pouring off the liquid, keeping the grid on the bottom. For the drying procedure a small amount of tert-butanol is left, letting the grid attach by capillary force to the wall of the tube, then sucking the fluid droplets left on the bottom with a pipet before closing the tube. The preparations are left for a short time in a cold place (below 25.5 °C), or briefly on ice, to let the tert-butanol solidify. The sample-containing tubes, with lid open, are brought to a vacuum drier (e.g. Savant Speed Vac Concentrator, with centrifugation off) to let the tert-butanol dry off. The grids are usually seen to drop to the bottom of the tubes when the drying is completed. The operation will not take longer than 10–30 min, depending on the amount of tert-butanol and the degree of vacuum used. The grids must be at RT when the preparations are lifted out from the vacuum dryer, to avoid water condensing on the specimens.

3.3 Freeze-drying

Freeze-drying (FD), like CPD, needs expensive equipment. The advantage of FD over CPD and drying from solidified tert-butanol is that the preparations are not dehydrated with organic substances that might be destructive, extracting membranes and denaturing proteins. Partial FD is used in the freeze-etching method, where cell preparations are coated with Pt–carbon to obtain replicas of, e.g. the cell cytoskeleton, showing sharp views of actin bundles and tubulin fibers in stereo.59 However, replicas are not useful for ETM 3-D reconstructions as the entire preparation must be transparent and not only a surface view. When FD is adapted for ETM, the time must be extended (1–3 h) so that the drying of the specimen is completed. The specimens must be prewashed with FddH2O to remove salts that will otherwise crystallize. If samples cannot maintain their configuration without salt, a volatile salt, e.g. ammonium acetate, is used at a concentration that keeps the specimen stable. Negative staining methods, e.g. of viruses, combined with FD
look superior\(^{(60)}\) for 3-D reconstructions, as the specimen configuration is maintained and not flattened as with AD.

In brief, the procedure to freeze the specimen for FD is analogous to cryo-TEM methods. The specimen is frozen in liquid nitrogen, with a container with cryogen (e.g. liquid ethane or propane), as an intermediate fluid that is functioning as an effective conductor, for rapid freezing of the water-embedded specimen into vitrified ice. The FD is performed by raising the temperature (to \(-80^\circ C\)). Drying out of the preparation at high vacuum will then be possible within a reasonable time,\(^{(60)}\) after which the preparations are ready for ETM.

### 3.4 Cryo-electron Tomography

Automation programs for collecting tilt series in ETM have made it possible, for 3-D reconstructions, to use single-axis cryo-ETM to collect tilt series of frozen vitrified samples, i.e. fully hydrated specimens, which are chemically unfixed, i.e. close to native state.\(^{(40)}\) However, with this almost ideal method for specimen preservation, a computer-controlled TEM and goniometer stage with cryo-holders, cooled with liquid nitrogen and accessories for preparing vitrified cryo-samples, are needed. A disadvantage is that the signal-to-noise ratio of the images usually tends to be poor, especially of unfixed and unstained specimens embedded in the vitrified ice. The noise in images is also difficult to abolish for specimens such as chromosomes as images collected in tilt series with axial tomography cannot be improved by any averaging image processing, as is possible with single particle or icosahedral virus tomography.\(^{(36,42)}\)

The procedure is as follows. Use isolated chromosomes mounted (section 2.2) on grids, coated with perforated carbon, or better with perforated plastic film,\(^{(61)}\) on, e.g. 50–75-mesh Ni or Au grids with colloidal (e.g. 5, 10, or 15 nm) gold markers for collecting tilt series. The idea with perforated-film coatings is to collect images of chromosomes that are preferably spanning a hole, embedded only in vitrified ice without a support, thus reducing noise and improving image contrast. Using 50-, 75-mesh or even single-slot grids, the prospect of viewing the whole tilting range from 0\(^\circ\) to 60\(^\circ\) is considerably improved. The grid–specimen is washed in HM or HC buffer (\(\leq 5 \text{ mM HEPES buffer}\)), in several droplets, before the grid, after excess buffer has been blotted off with filter-paper, is quickly dropped in a container, inserted in liquid nitrogen containing liquid ethane or propane, or better, in a mixture of ethane and propane (3:1) that prevents solidification of the freeze-transferring cryogens. The grids can be stored in liquid nitrogen until examination. The grid–specimen is installed in a liquid nitrogen-cooled cryo-specimen holder that protects the specimen from atmospheric humidity before cryo-TEM.

With cryo samples, automatic collection of the tilt series is the only way to avoid melting and beam damage of the specimens, as automation will shorten the exposure 10–100-fold compared with manual methods.\(^{(40)}\)

### 3.5 Section Preparations

Our 3-D reconstructions with ETM, accomplished on sections of epoxy-embedded material, are not so successful as with whole mounts. Many reasons may account for this difference. As mentioned, sections have been noticed to become up to 50% thinner,\(^{(4,36)}\) in the collection of tilt series data. If thinning takes place gradually during the collection, the reconstruction operations will severely fail, owing to unrestrained distortions of structures. The noise is more marked especially in thick sections than for whole mounts. However, thin sections also become thicker at high tilts (twofold at 60\(^\circ\))\(^{(52)}\) and images are blurred.

The advantage with the sectioning technique, however, is that most material can be embedded, sectioned and structures of interest selected that would otherwise be difficult to isolate or are too bulky to study as whole mounts.

Standard fixation methods used in EM are usually inadequate for chromosomes and nuclear structure studies.\(^{(8,22)}\) The fixation and staining methods that we have found applicable for section studies of chromosomes and nuclei are based on using RR in different combinations with GA, OT and, in dehydration before embedding in plastic resin, with UA (stain) in MeOH.

The procedure is as follows.

1. Specimens are fixed in 1–2% GA in 0.1 M NC buffer, pH 7.0–7.4, or in Ringer solution (RS), with (a) RR (750–1500 ppm) or (b) without RR, at RT, for 1–2 h or longer, washed in the NC buffer or RS.
2. Further fixed in 1% OT in the 0.1 M NC buffer or RS (2–4 h), RT, (a) with RR (750–1500 ppm) or (b) without RR, washed in the NC buffer or RS.
3. Stained in 0.1 M NC buffer or RS, (a) with RR (750–1500 ppm) or (b) without RR, for 24 h, at 4–8\(^\circ\)C, washed with buffer solution, briefly in water, before gradual dehydration in MeOH, then stained in 1% UA in MeOH [overnight (o/n) to several days, at 4–8\(^\circ\)C], washed in MeOH, transferred to absolute ethanol, propylene oxide, and finally to propylene oxide–Durcupan ACM (1:1), o/n.
4. Embedded in Durcupan ACM, epoxy resin (Fluka).

Controls: without RR, and with RR in the different steps and combinations.
The penetration of RR into nuclei and chromosomes can be checked in semithick section for phase-contrast LM.

Sections are cut with an ultramicrotome and mounted on grids according to standard EM thin-sectioning techniques. The sections on the grids are stained with Reynold’s lead citrate (10–30 min, in a Petri dish with solid KOH to avoid precipitation), washed with freshly boiled FddH2O and AD before examination in TEM.

Comments: importantly, to enhance the intracellular contrast with RR, it is to be used after the OT fixation (step 3). This is because OT fixation will destroy the semipermeability of cell membranes and RR will then penetrate and stain nuclei and chromosomes. Before OT fixation the intracellular penetration of RR is almost nonexistent. However, if high contrast is required, after staining with RR (step 3), postfixation with OT is added.

To study, e.g. interphase chromosomes, whole mounts of nuclei are too thick for ordinary 100–120-kV TEM. Thin sections must be used to collect the tilt series. Section thickness is, however, limited to <0.1 μm for 100–120 kV.

If thick sections must be used to incorporate spatial details, the embedding medium can also be removed. The sections are therefore changed to a kind of whole mounts. This improves the signal-to-noise ratio and makes the thick embedded material more permeable to electrons.

The material is fixed only with GA, before embedding and sectioning, and after removing the embedding, brought stepwise to buffer solution and prepared as whole mounts (section 2.4) or then processed as in bulk embedding for sectioning, i.e. fixed, stained, embedded and sectioned using standard fixation with GA or OT, or using the RR methods for chromosomes and nuclei, as presented above.

Gold markers are introduced only on the section-free side of the grid, to ensure that they do not float off when the embedding medium is removed. It may also be advisable not to poststain the sections with, e.g. Reynold’s lead citrate, that may form precipitates when the embedding medium is removed. The procedure for dissolving the embedding medium from sections is somewhat different, depending on the different embedding media used.62,63

Removal of resin from ordinary epoxy thin sections is carried out as follows:62

1. Preparation of the solution: prepare a solution of seven pellets of KOH in 100 mL of absolute ethanol (the color of the solution will be light orange–brown when ready, after 1–2 days).
2. Immerse the sections (0.25–0.5 μm or thicker), mounted on carbon–Formvar grids, in the solution for several minutes (to be time tested, depending on section thickness and epoxy resin used).
3. Wash in ethanol and MeOH, with several changes.
4. CPD (section 3).

If section material seems to be lost, PL-coated grids (section 2.2) are used to ensure better that the material will stick to the grids.

Note that the method seems to be mild enough to be used with immunological methods.62

In addition, for enzyme digestions a method has been introduced32 for immunostaining, e.g. interphase chromosomes. Isolated whole cells are encapsulated in agarose microbeads for the enzyme digestion and immunostaining procedures. Thick, resinless EM sections are obtained that are excellent for ETM purposes (applications in sections 2.3 and 7).

4 DATA COLLECTION

4.1 Recording of Tilt Series

Images recorded in TEM are two-dimensional (2-D) projections of a 3-D object. Owing to the large depth of focusing in TEM, all the details are usually in focus and superimposed in thick preparations, whole mounts and sections. Chromosomes lack symmetry, the kind of which is characteristic of icosahedral viruses. Thus, for 3-D reconstructions with ETM, single-axis recording of tilt projections is accomplished that after the alignment procedure is processed with the WBM and MEM.

A conservative prediction52 of the resolution (d) obtained with single-axis ETM is correlated with the number (theoretical) of projections (N) available (from 0 to ±90°) and the object thickness (D), and is given4 by Equation (1):

$$d = \frac{\pi D}{N}$$

The actual resolution realized is, however, difficult to estimate, as the number of projections is limited by the tilting range from 0 to ±60°. This tilting range is obtainable with standard specimen holders and goniometers in TEM. Special specimen stages and holders have been available earlier64 and recently introduced for cryo-EM, including new rectangular grids.65 Such grids with a ‘grill-like’ pattern have long been available, but the new ‘cryo-tilting grids’ are in a way improved because of the square shape, with rectilinear rims perpendicular to the tilting axis that will free the tilting procedure from shading grid bars. The disadvantage with these new grid holders is that there is no way of rotating the grid specimen. The rotation of the specimen is most important for oblong whole-mounted structures such as
chromosomes to orient them parallel to the tilt axis to record tilt series with optimal resolution in ETM.

4.2 Manual Recording

Although manual recording of tilt series in axial ETM will in the future be replaced by automatic recording (section 4.4), there are probably few laboratories today that have access to or can afford digitally controlled TEM equipped with automation facilities. Manual collection of tilt series is, after some training, a fairly quick procedure when recorded on EM photographic film plates [actually a faster procedure than recorded manually or automatically with a slow-scan charge-coupled device (CCD) camera]. The EM plates also have the advantage that the recorded area is very much larger than that covered by a CCD camera, and owing to this advantage for film plates, more and larger structures can be collected at higher magnification. This may be important not only for the structures under investigation but also for collecting gold markers for the alignment procedure, as there may not always be enough markers available in the area that the CCD chip covers. Manually, increments of less than 3° are difficult to accomplish in practice. We have found in any case that tilt series, from 0 to ±60° with a 3° increment, are sufficient for ETM reconstruction of whole mounts, and have become a standard for us. Testing tilt series, recorded with a 2° increment, has not shown significant improvements in reconstructions. However, reconstructions with a 5° increment give significantly less satisfactory results (however cf. Figure 1f, g, h).

Manual recording of tilt series is carried out as follows:

1. Check that the TEM is under optimal conditions, especially for 100 or 120 kV, which might differ from alignment settings at 60 or 80 kV.
2. Preferably, use a rotating grid holder, to adjust that the tilt axis is oriented optimally, i.e. along the length of the chromosomes.
3. Test, at low magnification, that the tilting from 0 to ±60° is attainable and not hidden, e.g. by grid bars. It is not absolutely necessary to cover the whole tilting (lacking one or even two images will not be a disaster).
4. Importantly, test that the preparation is stable, i.e. will not drift significantly during the recording. The stabilization can be improved by slight evaporation of additional carbon on grid specimens or by keeping the specimen in the electron beam, at low magnification, for some time (e.g. 5–10 min). If nothing helps to stop the movement, choose another place on the same grid for a new object, or change for a new grid specimen. Unstable specimens will easily ruin a reconstruction by blurring the whole or a great part of a tilt series.
5. Choose preferably the largest objective aperture, especially for whole mounts to achieve a high transparency, and a suitable magnification. According to our experience, the highest magnification with which we can collect a tilt series without significant radiation damage is about 60 000×. The electron beam must be kept as weak as possible to avoid radiation damage to the preparation. If possible, use the ‘minimum-dose focusing procedure’ that is available in some microscopes. This may be very useful for sensitive samples especially at high magnification.
6. A eucentric goniometer is preferable for collecting tilt series. The eucentricity of the goniometer must be adjusted as accurately as possible to be of use in collecting the tilt series. If goniometer adjustment is completed the specimen will not move and focusing will not change significantly, at least at low magnifications, when the specimen is tilted within the medium tilting range. Adjustment of the goniometer is, however, not very reliable, especially at high magnifications and tilting, and the focusing and shifting must usually be readjusted. If focusing must be corrected and if it is important to keep the magnification for each image in a tilt series unchanged, the focusing is adjusted with the z-control screw of the goniometer and by shifting the specimen back to position. If focusing is adjusted in a normal way during tilting, the magnification of the images will change. However, this incident will usually not be of much significance as most ETM programs will correct the scaling, i.e. magnification of each image, in the alignment procedure (section 5.1).
7. Collect the tilt series starting from 0 to ±60°, with e.g. a 3° increment (our standard). Some instructions recommend starting from one extreme tilt end and move through zero to the other tilt end, to avoid sudden jumps in data collection that may occur owing to insufficient precision of the goniometer.
8. It is advisable to adjust the exposure parameters for photographic EM plates so that the plates can be developed with a machine (e.g. Kodak, used for autoradiography films) available in most laboratories. With this procedure, a check of tilt series is rapidly accomplished, so that negatives with faults, not in focus or missing can be replaced while the specimen is still in position in the microscope.

4.3 Digitalization of Photographic Negatives

Digitalization, i.e. scanning of the tilt series, is necessary for computer processing. Scanning is a more laborious
procedure than manual collection of the tilt series data on photographic negatives. At present scanning is also largely manual. According to our knowledge, there is no scanning device available with automatic feeding of EM plates to the scanner. However, devices for 35-mm film strips and also framed slide pictures can be fed and scanned automatically but not film plates of the size used in EM (e.g. 6.5 × 9 cm).

One of the advantages with EM photographic plates, as mentioned, is the large area of the specimen that can be recorded. This may partly compensate for the tiresome scanning work, in comparison with the limited view covered with a CCD camera. In addition, there are more working prospects with film plates, as they can be scanned with the resolution needed and they allow the choice of other sectors of interest, on the large plates, for scanning and with, e.g. higher resolution.

Ordinary flat-bed scanners (e.g. Umax PowerLook 2000) that we use today have a maximum resolution of 1000 dpi (in both directions, optical and mechanical), i.e. a pixel size of 25.4 μm. Better but also much more expensive scanners are available, e.g. drum scanners, but the manual scanning is much too laborious (attaching many negatives on the drum) for the improved resolution. A high-precision flat-bed scanner (Zeiss, Scan1) is available that has a pixel size of 7.5 μm (precision 2 μm), but the price is much more than 20–30 times that of an ordinary flat-bed scanner.

At a magnification of a negative of, e.g. 50000 ×, scanning with 1000 dpi, the pixel resolution in the negative will accordingly be about 0.5 nm. This pixel resolution will exceed the conservative estimate of the resolution achievable, of ca. 5–8 nm, for an object with a diameter of, e.g. 100 nm (with 3° increments), according to Equation (1). However, the actual resolution frequently experienced is better than the conservative theoretical estimate.6(52) In theory, the resolution that is achieved, is sufficient for twice, or owing to the many procedures in the alignment, 3–4 times the original pixel size.6(52) Thus, oversampling with a 2–4 times smaller pixel size is of advantage for achieving in practice a needed resolution. As the grain size for EM photographic plates is, after chemical development procedures, estimated to be about 5 μm, this will in any case be the limit to the resolution that can be extracted from photographic negatives with digital procedures.

Scanning of the photographic negatives is carried out as follows:

1. Before scanning, dust from the negatives is removed with a soft brush, along with gentle breathing on the negatives, which will help, when the humidity is not high enough, to remove static electricity that might be a problem in dry conditions.

2. Up to eight negatives (size 6.5 × 9 cm), with shiny side down, are positioned on a flat-bed scanner (e.g. Umax PowerLook 2000).

3. The scanning is accomplished with a semiautomatic procedure together with automatic correction of contrast, of histograms, gamma values, etc. for each negative. Manual correction will take longer and the results will not necessarily be better.

4. The area and resolution (1000 dpi, optimal) are selected for the negatives and the title number for the image (corresponding to the tilt angle) and format used (e.g. jpeg) are recorded. The program automatically collects the data of the regions, according to the mentioned settings for each negative, in sequence.

Today, even with the advantages of semiautomatic scanning procedures, the completion of the scanning of all (e.g. 41, 3° increments) plates will usually take longer than the manual collection of the tilt series with TEM.

4.4 Automatic Recording

The automatic collection of tilt series data6(40) will in the future replace manual recording methods. Automation is the only manner for very sensitive specimen recordings such as cryo-EMT procedures (section 3.4), which involve embedding in vitreous ice, as the exposure to the electron beam is reduced 10–100-fold, as mentioned. Automated low-dose data collection of a tilt series uses adjacent areas for correction of changes in image shift and focus. The selected area chosen for the tilt series is recognized with the cross-correlation function process. The images are recorded using a high-performance digital camera system, i.e. a cooled slow-scan CCD camera (1024 × 1024 or 2048 × 2048 pixels).6(40)

Because of the cost, most laboratories will not have access to such facilities in the near future. However, to improve the resolution in ETM reconstructions, tilt series with smaller increment values are needed, e.g. 1°. The collection of tilt series with 1° increments is for practical reasons only possible with automatic data collection in digital format. Regardless of the preparative methods used, specimens suffer less radiation damage with automatic recording. In addition, the recording of the dynamic gray-scale range and avoiding image distortions are claimed to be superior with a CCD camera, in comparison with photographic film recording. All these improvements involving automatic data collection procedures are dealt with in a recent review.6(40)
5 ELECTRON TOMOGRAPHY METHODS

5.1 Alignment of Tilt Series

The tilt-series images collected must be most accurately aligned to be sufficient for ETM reconstructions, especially after manual recording and scanning procedures. Alignment of the tilt series can be accomplished without markers by using the cross-correlation function method as used in the automatic data collection process. However, before the cross-correlation or other automatic method has been better refined, the use of fiducial markers has proved to be a more accurate method for the aligning of tilt series data. A semiautomatic method is available, part of the program IMOD, for fiducial gold marking with the advantage that some gold tags may not need to be present in all the images. However, at first glance, the method appears more complicated than manual methods in use.

As mentioned earlier, different-sized colloidal gold particles on the grids are convenient for different magnifications. The minimum number to be marked is three (or four), ideally 10–20. Corresponding gold particles must be identified on all images of the collected tilt series, and preferably evenly distributed around the object to be reconstructed. Commercial gold markers are preferred, e.g. immunogold, as they appear around the object to be reconstructed. Gold particles must be identified on all images of the plane.

It may be useful to add that in the program we have developed, the gold particles can be situated on any side or level on the grid. They need not to be on the same plane.

Our program, JPEGANIM for SGI machines, used for the procedure has been appropriately designed for convenience, using interactive graphic interfaces with menus. The images of the whole tilt series are run as a movie, so each image can be sequentially viewed, back and forth, for rapidly recognizing the same gold particles in each image. The images can be contrast-enhanced temporarily or permanently, enlarged and moved to different regions when the image size exceeds the display, and processed otherwise, e.g. with unsharp masking and other filters. All these features aid in making the search and gold marking an easy and rapid operation.

When sufficient markers have been picked up and the files saved, the next step will be to test the alignment accuracy, using SOLVE from the menu in JPEGANIM. The program uses a conjugate gradient method that gives a set of overdetermined nonlinear equations that can be solved. After running, the program produces a plot with evaluation of alignment correlation, in pixels, with estimates for all images and gold markers used, as graphical scores. The refinement is accomplished, when necessary, by either removing the worst gold markers, in sequence, or trying to correct the position of poor gold markers in the images with the poorest scores and rerunning the program. A set of files is used in the next step for an evaluation, which includes corrected tilting angles, scaling, midpoints and the axial angles.

The alignment procedure will then be tested with ALIGN from the menu, e.g. on a small area with only one, or a few, gold particles. A midpoint is chosen and an area framed with the mouse, producing a sequence of pictures. The z coordinate for the midpoint is obtained by using the parallax method, i.e. marking the same point from two image tilts, the zero and an end tilting image, for the best accuracy. If the same point is difficult to mark in the endmost tilt, any other image can be used. An area is then framed for the object to be aligned, from the midpoint, and the program will produce a set of aligned images, twice the size of the frame chosen.

After running the program, the accuracy of the aligned images can be tested as a movie. The movie must run smoothly and keep the midpoint in place, to obtain an accurate reconstruction. Scaling, rotations and translation of the origin are all corrected by the program.

With the test procedure adequate, the object for reconstruction framed and aligned images saved, there is saved a file including the size of the object, in pixels, with corrected tilt angles and a filtering parameter used in the reconstruction procedure. Occasionally, if a set of aligned images show sudden jumps at certain places, the corrected tilt angles are replaced with the original angles chosen, i.e. ideal values with the increments for the tilt series. (Direct goniometer readings are more precise than computed values.) A realignment (2–3 times) procedure of aligned images may also be of help in correcting the alignment for difficult tilt series.

The aligned images can be viewed in stereo mode. Gold marking in stereo can be of great help for identification in difficult circumstances. The stereo mode is also most useful in the examination and interpretation of the original EM images as stereo movies, involving image processing, contrast and filtering procedures for comparison with the 3-D reconstructions produced with ETM.
5.2 Reconstruction Methods

The ETM reconstruction programs that are used need a set of accurately aligned images, i.e. Radon transforms. The aligned projections must be twice the area of the object region selected and, as mentioned, this is accomplished by the alignment program, to be implemented for an ETM 3-D reconstruction of the object.

A reconstruction is first produced, as a test, with the WBM, a quick procedure in SGI machines (Origin 2000, 128 R12k processors, 160 Gbyte RAM). If the reconstruction with WBM shows adequate results, the reconstruction is completed with MEM. Today we use COMPAQ AlphaServer 8400, eight EV6 processors, 12 Gbyte RAM. This is advantageous, as ETM with MEM is calculation intensive. (An earlier approximation, to compare the time taken by the programs to complete a reconstruction of a certain volume, was the following: WBM took the same time in minutes as MEM in hours. However, this match is not very valid for long, as the computers are steadily upgraded, and now the time needed for MEM processing is less than half of our earlier estimate.)

5.3 Weighted Back-projection Method

For some reasons, the programs available for ETM [e.g. IMOD (URL: http://www.soapdish.colorado.edu/imod/download.html) public domain program and SPIDER & WEB (URL: http://www.wadsworth.org/spider/doc/spider/docs/spider_license.html) by license] use WBM processing for ETM reconstructions. This may partly be due to earlier limits in computing capacity. Another reason might be that WBM as a rapid procedure has been determined, is an automatic procedure. The filtering parameter may be varied for an influence on resolution, smoothness or noise level of the reconstruction. However, in optimal cases, the appearance and resolution might be improved, but real improvements in reconstruction are more affected by the original quality of the tilt series and accuracy of the aligned images.

After developing and acquainting ourselves with the MEM procedure, we are now using WBM only as a rapid scrutiny method having in fact rejected WBM as a reliable reconstruction method. It is therefore unnecessary to go into the theoretical contents of WBM, as they have been presented earlier in detail.(28,36)

5.4 Maximum Entropy Method

The MEM was first introduced in an astrophysical context for filtering telescope pictures from noise, and the method initially presented significant improvements in image quality. The introduction into 3-D reconstruction procedures in structural biology was accomplished for the first time for chromosome studies, as earlier mentioned.(43) After this initial work, relatively few investigators in ETM have shown an interest in using MEM. This must be partly due to a lack of computing power and long processing times, or to poor evaluation methods used in viewing 3-D reconstructions.

In cooperation with Juha Ruokolainen (CSC, Center for Scientific Computing, Espoo, Finland), we decided to develop a MEM version of our own that was ready in early 1995. Later we extended our MEM also to a 16-bit MEM version that uses aligned 16-bit gray-scale images.(68) We became intensely aware of the need for better 3-D quality when we recognized the relatively poor accuracy of the WBM reconstructions viewed with the high-quality stereo procedures for ETM that we had developed earlier.(28)

MEM yields uniformly better reconstructions than WBM (cf. e.g. Figure 1f, g, h with Figure 5a, b), especially for whole-mount samples of chromosomes: they appear distinct in stereo viewing of the object with the volume visualization programs BOB and FUNCS (section 6.1). In addition, the noise level in WBM-reconstructed objects, as measured by $\alpha$-values, is often as high as 100 or more (of the 256 gray-scale levels) when using BOB or FUNCS. With MEM the $\alpha$ setting is much less, often close to zero.

Another way of comparing the quality of WBM and MEM reconstructions is to examine the shape of gold markers. With WBM the missing data wedges between 60 and 90° stretch structures along the electron beam ($z$-axis). According to the results, MEM corrects errors due to missing data more effectively than WBM, and the gold markers are clearly less oblong with MEM.

The disadvantage with MEM is the long calculation time needed for large volumes (e.g. $400 \times 400 \times 500$ pixels), only manageable for laboratories having access to supercomputer facilities. However, even desktop computers are today as fast as yesterday's supercomputers, so it should not be long before any laboratory will have the capacity to perform such computing. For smaller volumes (e.g. $100 \times 100 \times 100$ pixels) with an ordinary desktop computer this might already, or soon, be possible within a reasonable performance time.

A description of our MEM deconvolution is as follows,(68) Solution of the deconvolution with MEM aims to minimize the function that is composed by the square of the reconstruction error (Equation 2):

$$e^2 = \| p - Af \|^2$$

(2)
where \( \rho \) is the images and \( A \) is the back-projection operator, and by the regularizing term. The regularizing term in MEM is the entropy of the object to be reconstructed (Equation 3):

\[
E = - \sum_i \sum_j f_{ij} \ln f_{ij} \tag{3}
\]

where \( f_{ij} = f(x_i, y_j) \) is the object to be reconstructed. The quantity \( f \) must be positive. Combining Equations (2) and (3), the problem may now be presented as an optimizing problem: search for \( f_{ij} \) such that the expression \( A \) is at minimum (Equation 4):

\[
A = \sum_i \sum_j f_{ij} \ln f_{ij} + \lambda \| \rho - Af \|^2 \tag{4}
\]

where \( A \) is the Radon transform operator representing the reconstruction function as back-projections of images. The Lagrange coefficient, \( \lambda \), is a regularization parameter, which weights the reconstruction error with respect to the entropy.

As mentioned, the experiences with MEM are promising. For example, noise is notably eliminated, and so is the wavering that the Fourier transformation also causes. For example, noise is notably eliminated, and so is entropy.

\[
\begin{align*}
\text{As mentioned, the experiences with MEM are promising.}
\end{align*}
\]

Our MEM procedure (MaxEntropy) is almost as transparent for the user as WBM. In the file that is created in the saving of the aligned images, the regularization parameter is added after the filtering (default) value. If problems appear, often seen as regions of minor stripes or bands, then this regulating parameter is tested with other values until the reconstruction has been refined to remove the minor distortions.

There is an additional regularization parameter for our 16-bit MEM. This 16-bit MEM, as yet not much used, will be especially useful when 16-bit gray-scale images are accessible with high-performance 16-bit CCD cameras with automatic data collection of tilt series, especially in cryo-ETM procedures.

As already mentioned, MEM is executed on a COMPAQ AlphaServer (8400) SG 140 (eight processors, 12 Gbyte RAM), especially for large volumes. However, the data have to be converted to be usable for viewing the volumes in the SGI machines, as the bytes in the Alpha machines are in a different order. This inconsistency is corrected by using a conversion program in the Alpha machine to make the volumes applicable for SGI machines.

Actually, a set of different conversion and other subprograms are repeatedly used. There is no reason to go into all the details, as different programs and machine set-ups may require different modifications.

### 5.5 Dual-axis Tilting Method

In conventional single-axis tilt series, the tilts used are limited to the range from 0 to ±60°. As already mentioned (section 4.1), grid holders are available for increasing the tilting range, e.g. from 0 to ±70° (or even up to 80°), but at the highest tilting ranges occultation easily occurs, and for sections the thickness will in general become too large, especially at very high tilts, e.g. two times thicker at 60° and three times thicker at 70°.\(^{52}\) for collecting reliable data with conventional 100–120-kV TEM.

Methods have recently been introduced to reduce the missing data wedge, e.g. between 60 and 90°, by using dual-axis tomography tilt series.\(^{69,70}\) The two programs transform the missing wedge to a missing pyramid, and combine somewhat differently the two orthogonal single-axis tilt series obtained by 90° rotation.

The dual-axis tilting approach has shown improvements in some situations, e.g. membrane vesicles appear restored from distortions in comparison with the single-axis method. Detailed instructions on the procedure, with or without a specimen-rotating grid holder, have recently been prescribed.\(^{52}\)

It seems doubtful if any improvements can be obtained for oblong structures such as chromosomes and chromatin fibers, as microtubules oriented perpendicular to the tilt axis fade and are lost in reconstructions.\(^{52}\) In any case, improvements have been claimed, at least in some cases, also for microtubules.\(^{70}\) According to our experience, long structures, e.g. microvilli, when tilted perpendicular to the tilt axis, appear very unsharp and faded along the reconstruction. It is obvious that the dual-tilting axis method is useful only for fairly rounded objects that need not be specially oriented for collecting tilt series.

In our experience, to test cryo-preserved preparations (in cooperation with H. Cheng, Karolinska Institute, Stockholm, Sweden, and M. Marko, Wadsworth Center, Albany, NY, USA) using our MEM procedure and combining the dual-axis tilt reconstructions with IMOD,\(^{70}\) no clearly distinct improvements emerged. However, all possible refinements have not yet been accomplished and the original tilt series from the sections used were, for some unknown reasons, difficult to align accurately. Such inaccuracies may have contributed to the unsatisfactory result, as the improvements usually detected with a dual-axis tilting method seem to be the most delicate\(^{70}\) and advantageous when all basic parameters are refined to the optimum.
6 RENDERING OF RECONSTRUCTED CHROMOSOMES

6.1 Visualization of Three-dimensional Reconstructions

When a chromosome reconstruction has been completed with WBM or MEM, there are several ways to visualize 3-D volumes. In any case the reconstruction must be in the right format for the program. For such conversions another set of programs are used.

As indicated, we regularly use two programs for SGI machines, BOB (a public domain program, University of Minnesota, Graphic Visualization Laboratory, Army High Performance Computing Research Center) and FUNC,\textsuperscript{(28)} that efficiently display volumes of 3-D reconstructions of, e.g., chromosomes in stereo mode.

The SGI workstations (Octane, 1 Gbyte RAM, and Onyx2, 4 Gbyte RAM with 4 MIPS R10000 processors and InfiniteReality2E-graphics), with high-frequency displays, and provided with liquid-crystal stereo (Crystal Eyes) eyeglasses, synchronized by an infrared light device controlled by the computer, show images in color stereo mode. According to our experience, stereo viewing is the only way of even beginning to comprehend the geometry and 3-D structure of chromosomes (Figures 1f, g, h, 8a, c, 9a, b and 10b, c). Other methods might involve

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{image}
\caption{(a) Chromosome scaffold, stereo pair of 3-D reconstruction with MEM, section 5.4. [AA-isolated chromosomes from HeLa cells, prepared as in section 2.4, procedure: 1(b) and (c), then treated as in section 2.3, with DNase and RNase digestion; then as in section 2.4, Procedure 1(d) and dried from tert-butanol, section 3.2.] Typical coiling appears in chromosomes, although they are depleted of histones and DNA, showing that scaffold elements are maintaining the coiling. The pattern and structures that can be detected are wholly in agreement with the unified loop-and-rosette chromosome model (Figure 1). The unified model gives predictions about the structure of the chromosome core regions, i.e. scaffold, in all details. Ring-like structures that are in agreement with the size of cyclomeres are detected (arrows) in the chromosome scaffold. In addition, gyres of the scaffold macrocoils measure to fit two rows of cyclomeres, e.g. in a zigzag pattern [cf. zigzag ribbon model for arranging nucleosomes in the 30 nm chromosome fiber\textsuperscript{[4,17]}, although minor coils,\textsuperscript{[25]} e.g. solenoid arrangement of cyclomeres, can also be seen closer to the centromere region, indicating that the structure of the chromosome coiling is versatile. (b) Hard copy, i.e. solid 3-D plastic model (section 9) produced earlier\textsuperscript{[28]} from a WBM 3-D reconstruction. Coiling and many of the ring-like structures are found in the hard copy and importantly arch-like bends (arrow) that the unified loop-and-rosette model also predicts (cf. Figures 1b and 2c). (c) Immunoblottings with antibody (Ab) to H1 and H2b (antibodies to histones H1 and H2b kindly provided by Dr M. Bustin, NIH, Bethesda, MD, and Dr B.D. Stollar, Department of Biochemistry, Tufts University School of Medicine, Boston, MA, USA, respectively): 60% AA-isolated chromosome pellet, 60% AA-isolated chromosome pellet that has been further boiled (0.5–2 min) in 50% AA, and as positive controls the supernatant of 60% AA extract and of whole cells. LMW (low molecular weight) protein markers (Bio-Rad). Text in each sample column. (d) AA-isolated chromosomes fluoresce brightly with the DNA-specific fluorochrome DAPI. Digestion with nucleases DNase I and RNase A (section 2.3) remove all detectable fluorescence, but chromosome scaffolds retain their original shape and can be seen in LM (text in each picture). [(a–d) partly published in Engelhardt et al.\textsuperscript{[28,54]}](e) Stereo series of the chromosome scaffold arm [see (a)] with 10° increments around the tilting axis for each row, to observe the chromosome coiling from various directions. Ring-like structures of cyclomere size (arrows) are present. Thicker gyres (arrowheads) of the scaffolding coils seem to be fitted with two rows of cyclomeres in a zigzag pattern as suggested in the unified loop-and-rosette chromosome model [Figure 1, and cf. (a)]. [There is resemblance to intact chromosomes, with histones and DNA, having ‘large-scale domains, roughly 100–130 nm in width’, as described in EM tomographic sections of metaphase and telophase chromosomes by Belmont;\textsuperscript{[30]} cf. his Figure 1.]
\end{figure}
underestimation of the structural complexity and be rather pointless in really getting to grips with the 3-D reconstruction by ETM.

The 3-D reconstructions of chromosome are shown as translucent objects, regulated by alpha blending, and color may be introduced for different gray-scale ranges, composed of voxels, the size and density correlating with the pixel resolution of the original EM image projections. Viewed in mono and gray-scale, the reconstructed 3-D chromosomes look identical with the original 2-D EM images. Gray-scale viewing in stereo mode may actually be a more correct way to resolve complicated structures than replacing gray-scale values with various colors; although the colors look inspiring, they may actually confuse, not only beginners, rather than clear up complex structures. However, replacing gray-scale values with different colors can effectively intensify minute density differences for detection and analysis (e.g. Figure 9b).

Figure 8 (Continued)
Figure 9  (a) Stereo pair of MEM 3-D reconstructed chromosome scaffold of a small (HeLa) chromosome (prepared as in Figure 8a) visualized with BOB (section 6.1; cf. Figure 1f). Coiling is obviously not prevalent in this size class of chromosomes, as it would require a certain length. However, scaffold fibers can be studied in more detail. Scaffold fibers appear as disordered fibers and arches or have an open ring-like form (arrow), as the loop-and-rosette model predicts. In the background fiducial gold markers (red color) are seen. [Reproduced from Engelhardt and Ruokolainen\textsuperscript{54}]. (b) Detail from (a) (thick arrowhead), stereo series of scaffold fibers rotated along the tilting axis, with 10° increments. Along the fiber perforation-like structures are obvious (light blue). A 10-nm gold particle (red) is visible among the fibers. A description of the perforation pattern of the fiber structure has been presented earlier\textsuperscript{54} as peripherally located toroid-like structures of about 8 nm in outer diameter with a central hole of about 4 nm, but also open toroids could be detected along the spirally wound scaffold fibers. It was suggested that the perforations (toroids) are manifestations of topoisomerase II (a main scaffold protein). [Stereo pair in (b) reproduced from Engelhardt and Ruokolainen.\textsuperscript{54}]
Furthermore, a 3-D reconstruction can be rotated and moved in any direction, enlarged, sliced and details can be cut out for closer viewing, or joining of voxels can smoothly display large volumes.

We use the programs for different aims. BOB is an easy and fast way for regular viewing of large and small volumes in stereo mode. FUNCS is slightly more difficult to use, but includes more features, such as introducing different-colored lights from different directions, interpolation of volumes or showing the volume as surface view (isosurfaces). Most importantly, FUNCS allows high-quality animations (section 6.2).

Other methods, such as sectioning the volume from any direction into 2-D slices that can be viewed in series, as a slow or rapid movie, also in stereo mode, or from all directions simultaneously, are available for dissecting and analyzing reconstructions. These and other features are found in such programs as IMOD and SPIDER & WEB (section 5.3).

6.2 Producing Stereo Animations from Three-dimensional Volumes

The problem, when viewing high-resolution reconstructions of, e.g. chromosomes, is that volumes (over 200 x 200 x 200 pixels) become slow, i.e. scenarios have to be recalculated by the computer, e.g. when the image is enlarged or the direction is slightly changed, e.g. in tracking structures in detail. The recalculation takes time, relative to the size of volume, which causes difficulties in following details when minor structural changes take place, i.e. causes loss of the track.

New effective high-end SG1 workstations (as detailed in section 6.1) are available that may solve the calculation problems at least up to some volume sizes. However, the programs have to be updated (rewritten) for new workstations.

A much simpler and effective way to solve this kind of problem, which we have used earlier, is by creating high-resolution animations\(^{(28)}\) around an axis, usually the tilting axis (Figures 1g, h, 8e, 9b, 10c). These animations can be produced from any size of reconstructions that are recovered with ETM, including interpolations and illumination from different directions, both of which improve significantly the appearance of details. Animations are produced with FUNCS, around the tilt axis with, e.g. 10° increments and three-time interpolations. However, animations with smaller increments, e.g. 1–5°, improve the tracking of details considerably. Depending on the size of the volume, the animations are produced in less than 1 h up to o/n.

Figure 10 (a) Tilt picture (+45°) from the tilt series (0 to ±60°, in 3° increments) of chromosome scaffold (prepared as in Figure 8a). Overhanging scaffold fibers are seen originating from the chromosome scaffold torn from the carbon–Formvar film, visible at the picture base with 10-nm gold particles. The freely dangling scaffold fibers were used for the 3-D reconstruction to achieve the highest resolution. After high-resolution scanning the pixel size corresponds to 0.4 nm in the tilt series, collected at 58 000× magnification. [Another tilt picture from this series published in Engelhardt and Ruokolainen.\(^{(54)}\)] (b) Stereo pair of MEM 3-D reconstruction of freely hanging scaffold fibers. Fiducial 10-nm gold particles are seen tagged to the fibers. (c) Stereo series, with 10° increment, of MEM 3-D reconstruction of top part [arrowhead in (a) and (b)] of the scaffold fibers, from high-resolution animation series (interpolating pixel vs voxel size to 0.1 nm). In stereo, an impression is made of a slender mostly peripheral lace-like structure, demarcating sharply the scaffold fiber periphery. [Outer mesh diameter 3.5 nm, inner mesh diameter and thickness about 1.5 nm. These values are rough as they are on or below the limit of the ‘conservative estimate of resolution’,\(^{(52)}\) which is about 3 nm, Equation 1.] Stereo viewing reveals that the gold particles are inside the stretched fibers. This confirms that the fibers are very empty indeed. If the lace-like covering is real it could be part or derivative of the NE lamina that has recently been shown to be found inside the nuclei with IEM\(^{(32)}\) after DNase digestion. [Stereo pair of this series published in Engelhardt and Ruokolainen.\(^{(54)}\)]
The images of an animation are saved in high-quality jpeg format and viewed with JPEGANIM, in stereo mode. Also, as already mentioned, from the menu of JPEGANIM, the movies can be magnified, moved to different regions, and structures can be measured with great precision, run with different speeds or very accurately by stepwise moving, smoothly, frame after frame. With these animations, the stereo viewing is not disturbed by blurring recalculations as the animations are sequences of ready-processed images that are all in the memory of the SGI workstation (as detailed in section 6.2).

6.3 Computer-aided Virtual Environment
Another means of 3-D visualization of volumes that we have recently used for viewing 3-D reconstructions of chromosomes, usable also for an audience, is the computer-aided virtual environment (CAVE) (available, e.g. at the Helsinki University of Technology).

The CAVE is a room, with wall-sized displays (three walls and the floor), controlled by a high-end SGI workstation (Onyx2, Infinitereality, 1 Gbyte RAM and four R10000 processors). High-end precision projectors, controlled by the SGI workstation, project the images of the volume on the walls. The viewers stand in the middle of the CAVE with liquid-crystal stereo (Crystal Eyes) eyeglasses. The rotating volume can be seen in 3-D form from all directions and from within at high resolution.

No doubt the 3-D view obtained is most impressive with very accurate details, as the whole volume is seen with all details and not limited by frames, as happens with
ordinary computer displays, when the object is magnified. The impression is that this is not only an excellent method for showing 3-D reconstructions for a group, to promote meaningful discussions among researchers, but also an important tool for perceiving structures that cannot be easily displayed in other ways.

7 IMMUNOELECTRON TOMOGRAPHY

The ultimate goal, in structural studies and particularly in 3-D reconstruction studies with ETM of biological specimens, would be to recognize different proteins, nucleic acids and other macromolecular assemblies straight from their structural 3-D configuration. Before this ideal goal, achievable perhaps in the distant future, we have to use some other means of identification, such as immunological methods. Immunological methods work strikingly adequately in locating specific proteins at LM and EM levels. We have recently developed IET methods. In principle, these methods do not differ much from ordinary IEM methods. We have used whole-mounted cells grown on EM grids for IET. Primarily, whole-mounted cells are not usually used in IEM in the way that thin sectioning or whole mounts of protein assemblies or objects of comparable size have been used. In whole-mounted cells or objects such as chromosomes, the immunolabeling would be difficult to distinguish because of the thickness and superimposition of immunolabeling in the 2-D images in TEM of such samples.

However, whole mounts are very suitable for IET. Instead of attaching gold markers on the grids for aligning the tilt series, immunogold labeling will be most adequate for the alignment. The different-sized immunogold markers will identify different proteins on the same preparations.

The problems in the development procedures were obtaining clean control preparations and preserving the cell ultrastructure, antigenic properties of the proteins and making cells permeable to immunogold labeling. In our IET reconstructions, we could easily see 5- and 10-nm gold conjugates. In addition, in distinct reconstructions, 1.4-nm immunogold (Nanoprobes Inc.) was detected especially clearly in overhanging microvilli, where the carbon–Formvar support had been torn away. This was to accomplish a set of high-resolution tilt series, so that the resolution was not obstructed by the support (Figure 11).

It remains to be seen how IET works for whole-mounted chromosomes, but we see no prominent difficulties. The steric hindrance by DNA present may cause penetration problems for immunogolds used. Thus, DNase-treated chromosomes, i.e. isolated chromosome scaffolds, would be the primary target in identifying scaffold proteins in 3-D reconstructions. The antigenicity of proteins may be hampered by 60% AA isolation of chromosomes, so that a more physiological method for chromosome scaffold isolation might be immunologically more suitable. In any case, 60% AA-extracted histones had not lost their antigenic properties (Figure 8c) as shown in immunoblottings.

IET procedures modified for whole-mounted chromosomes are as follows. The starting material is chromosomes or chromosome scaffolds mounted on PL-coated or glow-discharged carbon–Formvar–Ni grids (section 2.2). The treatments are performed on Parafilms, with drop-sized depressions on wet filter-paper in Petri dishes (section 2.3). Washings and incubations are performed at RT, preferably on a tabletop shaker (gentle shaking). All solutions are filtered through a 0.22 µm (Millipore) filter. Small amounts that are difficult to filter are centrifuged, e.g. Ab mixtures, GA and OT solutions.

1. Prefixing in 0.125% GA in HM solution, 15 min.
2. Without prefixing:
   Wash in HM solution, several drops.
   Preincubation: wash and incubate o/n in TXHS (0.05% Triton X-100, 30 mM HEPES, pH 7.4, 0.1–0.5 M NaCl, 20 mM KCl, 5 mM MgCl₂, 20 mM glycine, 0.02% NaN₃), with (a) 0.5% fish gelatin (FG), or (b) no FG, 1–2 h at RT, and/or +4°C o/n.

   (a) Incubation in primary Ab mixture (1 + 2):
      (i) Rabbit polyclonal Ab for protein 1 (LM-checked, e.g. 1 : 50–1 : 10³).
      (ii) Mouse monoclonal Ab for protein 2 (LM-checked, e.g. 1 : 25).
   Diluted in (a) TXHS + FG or (b) TXHS, 1–2 h at RT, and +4°C o/n.
   Wash in TXHS, in several drops (1–10 min per drop).

   (b) Incubation in secondary gold-conjugated Ab mixtures; examples:
      (i) Mixture: goat anti-rabbit (GAR)–10 nm gold (1 : 25 dilution, Sigma) with GAR–1.4 nm gold (1 : 25 dilution, fluoronanogold, Nanoprobes Inc.) and goat anti-mouse (GAM)–5 nm gold (1 : 25 dilution, Sigma), diluted in (a) TXHS + FG or (b) TXHS, and/or
Figure 11 Examples of IET. Microvillar proteins in MRC-7 cells. Overhanging microvilli (without carbon–Formvar support) of MCF-7 cells, will be representative samples of IET methods developed that may analogously be used for IET chromosome studies (section 7). (a) Stereo pair (BOB, cf. Figure 1f) of microvillar ezrin labeled with 10-nm gold particles. The specimen was postfixed with the GA, OT, TA method (section 7). TA was used to minimize shrinkage of the samples after GA fixation (sections 2.4 and 7). The raw IET data (sections 4.2, 4.3 and 5.1) were processed with MEM (section 5.4). The 3-D preservation using TA shows more substructural details than without TA [cf. (d)]. (b) A stereo pair image [as in (a)] of microvillar ezrin and mucin. The specimen was postfixed with the TA method [as in (a)]. Ezrin was labeled with 10- and 1.4-nm gold conjugates and mucin with 5-nm gold conjugates. MEM 3-D reconstruction methods were used [cf. (a)]. Ezrin labeled with 1.4-nm gold particles is marked by arrows. Arrow with ribbon shows clusters of 1.4-nm gold particles. The intermediate-sized particles depict mucin labeled with 5-nm gold conjugates. (b1) Detail of (b) showing a stereo pair of 1.4-nm gold clusters (arrow) at higher magnification. (b2) Details in a single 10-nm gold particle. (c) IET reconstructed with WBM (section 5.3), for comparison of the same microvilli as in (b) with MEM procedure. Gold labels are seen but the 3-D reconstruction is less sharp and more noisy. (d) Stereo pair image [as in (a)] of MEM 3-D reconstructed microvillus as a control without TA (section 7). Ezrin was labeled with 10- and 1.4-nm gold conjugates and mucin with 5-nm gold conjugates. The 1.4-nm gold conjugates are present but more difficult to detect than in (b) with TA (presumably the detection of 1.4-nm particle size is more difficult owing to the shrinkage caused by GA fixation and CPD, which the treatment with TA seems to prevent. [Reproduced from Engelhardt et al.]
(ii) Mixture: GAR–10 nm gold (1:25 dilution) with GAM–5 nm gold (1:25 dilution) and GAM–1.4 nm gold (1:25 dilution), in (a) TXHS + FG or (b) TXHS.
Incubation: 1–2 h at RT and 4°C o/n.
Wash in TXHS, several drops (1–10 min per drop).
Wash in HM, several drops.

3. Postfixing: 1.25% GA (1 h–o/n) in HM, (a) add OT (from e.g. 1% stock solution) in 0.1 M NC buffer, pH 7.4, to 0.3% OT as a mixture with GA in HM, 1–5 min, RT; (b) no OT.
Wash in HM, several drops.

4. TA: (a) 1% TA in 0.1 M NC and HM (1:1), 5 min (for whole-mounted cells 1 h–o/n); (b) no TA.
Wash in HM, several drops.

5. Dehydrated in 30, 50, 75, 100% MeOH.

6. Stain in 0.001–0.002% UA in MeOH (30 s), wash in MeOH.

7. CPD or other 3-D-preserving drying methods (section 3).

Controls: In IET controls, control (preimmune) serum was used or primary serum Abs were omitted and samples were postfixed only in GA (with or without TA), with no UA before step 7.

LM: immunofluorescence fixed in 3.5% paraformaldehyde in HM, using secondary GAR–fluorescein isothiocyanate (FITC) and/or GAM–Rhodamine, according to standard protocols. In principle the very same methods would be sufficient.

In addition, LM in situ hybridization techniques are standard procedures only to replace, e.g. after the first biotin–avidin amplification procedures, the second one with gold-conjugated avidin, and replacing AD with, e.g. CPD (section 3).

FISH (fluorescence in situ hybridization) preparations are frequently contaminated with background signals that may be difficult to eliminate and spoil the accuracy required with in situ hybridization for EM preparations. In addition, cytoplasmic fragments regularly contaminate LM and microspreading preparations in EM studies.

It is therefore essential to strive for chromosome purification methods where cytoplasmic contaminations are eliminated, to be useful for in situ ETM. In addition, it is important to refine blocking methods to remove any background and unspecific labeling.

Superimposing contaminants and background labeling may disturb ordinary in situ hybridization EM preparations. ETM has the advantage that from the 3-D reconstructions, superimposed contaminating materials may be eliminated, as chromosomes with specific labeling can be cut out from surrounding material with ETM procedures and the pure 3-D chromosome reconstructions can be analyzed separately in detail.
9 HARD COPIES, PRODUCTION OF SOLID THREE-DIMENSIONAL MODELS

Hard copies, e.g. photographic prints, are produced of computer images, and hard copies of 3-D reconstructions of, e.g. chromosomes can also be produced, as we showed years ago. This manufacturing procedure is called rapid prototyping technology (RPT). Today also the term laser stereolithography (laser photo-polymer technology) is used, including various other manufacturing procedures.

The solid 3-D model produced by the RPT method of our reconstructed chromosome scaffold is presented with all details. Our primary 3-D reproduction had to be supported by solid bars to maintain the spatial relationship of various parts. The material, from which the model is manufactured is nontransparent and somewhat fragile. The height is 13 cm and the width and thickness are relative to the computer reconstruction. Also, most of the details, although complicated, are reproduced with comparative accuracy that is limited only by the nontransparent material that is less useful for structural studies.

The technology to reproduce solid 3-D models of 3-D reconstructions is advancing rapidly. This will bring us solid 3-D models of more transparent material with different colors to accentuate, e.g. internal structures with the same density, i.e. isosurfaces. Such hard copies will be a great aid for complex structural studies that chromosome structures particularly require.

We must admit, however, that although the impression of the original chromosome scaffold appeared as a typical chromosomal coil, and the impression of a coil structure prevailed in the viewing of the 3-D reconstruction in the computer, the solid 3-D model could neither verify nor disprove the coil configuration.

Actually, we can realize that this apparent conflict may arise because the scaffold is not a uniform structure but composed of thicker and thinner segments, i.e. coiling does not look very regular at a closer look. Owing to the irregular thickness, the coil appears also dually as sequences of bands and interbands, although the bands are actually just thicker clusters of the coiling scaffold structure and the interbands are thinner regions of the coiling scaffold, as the loop-and-rosette model predicts.

The higher level structure of chromosomes is indeed very complex. Neither the 3-D reconstruction (performed with WBM) nor the solid 3-D model allowed unambiguous structural interpretation of configurations. Further, the problematic situation of chromosome coiling (cf. Figures 1f, g, h and 8a, e) resembles the level of the 30-nm chromatin fiber. Chromosome structures at all levels are much more complicated than we think and the methods are not yet sufficiently developed.

10 METHOD DEVELOPMENT

A program and instruments to collect tilt series automatically for ETM are now available. An accurate automatic alignment procedure, at least as accurate as the fiducial gold markers, would also be very useful. The two programs would constitute the all-automatic ETM kit. The system would use a supercomputer facility in connection with a computer-controlled TEM. Not too many obstacles are likely to be in the way of such a development. Whenever possible, the cryo methods would be used on unfixed and unstained specimens embedded in vitrified ice. The cryo-TEM techniques are fast and specimens are relatively easy to prepare and fully hydrated, i.e. close to the native state. However, the problem of noisy images in cryo preparations must be solved with filtration programs. We recently succeeded in eliminating at least partly the noise from some cryo-embedded preparations, with programs that we developed. The noise problem in cryo-specimens may thus be tractable.

A viewing room and facility, such as CAVE or VR (virtual reality) CUBE (Royal University of Technology, Stockholm, Sweden), will be indispensable for thorough analyses of high-resolution 3-D reconstructions.

With chromosome structure as an example, we realize that many structures are too complex for comprehension with present 3-D reconstruction methods, including hardware solid 3-D models. Thorough analysis with methods and programs may be useful, e.g. for tracking specified structures manually, semiautomatically or automatically, in 3-D form, from section to section. Such tracking studies on whole-mounted chromosomes were started as early as 1988 with an automatic algorithm included in the program IMAGIC. Semiautomatic programs for this purpose are now available, such as STERECON and TINKERBELL and in the framework of IMOD.

A new exciting method (SITUS) (a public domain program), available for testing, combines protein data from high resolution X-ray crystallography, available from the Protein Data Bank, with 3-D reconstructions with ETM. The program, which makes use of neural nets, searches the known protein configuration, as ‘fingerprints’, in the volume and, if found, displays its localization and orientation. This method would yield an identification method for proteins, without immunological techniques, and reveal their structure in the ETM-created volume at atomic resolution.

ACKNOWLEDGMENTS

For acquainting me with the practice of electron tomography, in 1989, I thank Lisa Borland, Marin van Heel.
and Professor E. Zeitler, Head, Fritz Haber Institute, Berlin. Initial tips on MEM and further instruction on tomography methods, from Docent Ulf Skoglund, his tomography group (Lars-Göran Öfverstedt and Hans Mehlin) and Professor B. Daneholt, Head, Department of Cell and Molecular Biology, Karolinska Institute, Stockholm, are gratefully acknowledged. The visit to Karolinska Institute in 1993 was supported by EMBO and Nordiska Ministerrådet. Financial support from the foundations Maud Kuistilan Säätiö and Oskar Öflunds Stiftelse is gratefully acknowledged. At CSC-Scientific Computing, Espoo, Finland, the professional skills of Juha Ruokolainen, in both programming efficiency and physical theories, have been indispensable. Jukka Heikkonen of the Laboratory of Computational Engineering and Jorma Laaksonen of the Laboratory of Computer and Information Science, Helsinki University of Technology, have cooperated in the development and refinement of programs. For working facilities, for advice and for comments on the manuscript I thank Professor Antti Vaheri, Head, and Professor Carl-Henrik von Bonsdorff, Haaertman Institute, University of Helsinki. The manuscript was thoroughly discussed with and scrutinized by Kalevi Pusa, who made a number of useful suggestions.

Fluorescence In Situ Hybridization

Thomas Haaf
Max-Planck-Institute of Molecular Genetics, Berlin, Germany

Fluorescence in situ hybridization (FISH) is a technique used to directly visualize specific DNA sequences on morphologically preserved cytological specimens such as metaphase chromosomes, interphase cell nuclei, and extended chromatin fibers or DNA molecules. The general usefulness of radioactive in situ hybridization was greatly hampered by the safety measures required when using radiolabeled probes and the rather long time (up to several weeks) needed for autoradiographic analysis. The development of powerful FISH protocols, in which unspecific hybridization of interspersed repetitive sequences contained within genomic DNA probes is suppressed, allowed for the first time the rapid visualization of single-copy sequences and whole chromosomes, and thus marked a turning point in the experimental and diagnostic application of in situ hybridization. The major advantages of FISH over radioactive methods are increased spatial resolution, speed, probe stability, and the ability to detect multiple chromosomal targets in different colors. Indirect FISH uses hapten-labeled DNA probes in combination with immunocytochemistry (secondary detection reagents). Direct methods use fluorochromes directly coupled to nucleotides in the probe DNA. Probe labeling is most easily accomplished by nick translation or other enzymatic labeling procedures. For hybridization of the modified probe DNA to chromosomes and cell nuclei, both probe and target DNA must be denatured. In the hybridization reaction, complementary single-stranded sequences in the probe and chromosomal target are allowed to reanneal. After posthybridization washing and immunocytochemical detection of in situ bound hapten molecules, a specific fluorescent signal is produced at the hybridization site, which can be viewed by eye through the epifluorescence microscope. Digital imaging and computerized storage of images have largely replaced photography and greatly facilitated data analysis and image handling. However, most importantly the success of FISH experiments depends on the quality of the chromosome preparations and the size of the chromosomal DNA target. When large-insert (>30 kb (kilobase)) clones or complex DNA libraries are used as FISH probes, between 80% and 100% of the target chromosomes carry visible hybridization signals. This percentage drops to only a few percent when 1 kb or less of a single-copy sequence is hybridized. In the past few years several technical advances have expanded FISH applications. Comparative genomic hybridization (CGH) of differentially labeled tester (tumor or patient) and normal reference DNA allows the analysis of all genetic imbalances (chromosomal gains and losses) in a tester genome within a single experiment and without the need to prepare chromosomes from the tester. Combinatorial probe labeling and multicolor FISH are used for the simultaneous detection of 24 (or more) chromosomal targets in different colors, and therefore can provide a comprehensive picture of extensively rearranged tumor karyotypes. The DNA resolution of FISH has been dramatically increased (from several megabases (Mbs) to several kilobases) by hybridization to
extended chromatin fibers and linearized DNA molecules. Fiber FISH and molecular combing allow one to order probes relative to each other, to orient probes within a contig, and to determine the degree of overlap or gap size between different probes. Overall, FISH has become an increasingly popular method with a broad spectrum of applications in cytogenetics, genomics, tumor biology, and many other research areas. It has a bright and colorful future.

1 INTRODUCTION

FISH has become an extremely powerful and widely used experimental method over the past 10–15 years, and has created an entirely new field, molecular cytogenetics. It can be used to localize specific DNA sequences on chromosomes, interphase nuclei, and experimentally extended chromatin fibers or DNA molecules. In situ hybridization techniques were originally developed in the late 1960s, at a time when only radioactive labels were available for nucleic acids and cloned DNA probes did not yet exist. Enzymatic labeling of nucleic acids with biotin and other haptens offered several important advantages over radioactive in situ hybridization. Nonisotopically labeled DNA sequences are stable for years and the hybridized probes can be evaluated directly at the microscope without autoradiography. This not only significantly shortens analysis time and avoids hazardous radioactive waste, but there is also something very satisfying about a fluorescing image. The advance of molecular cloning and, more recently, the launch of the human genome project have led to an explosion in the number of DNA probes that are available for in situ hybridization to visualize a chromosome or chromosome region of interest. In addition, FISH applications have been greatly expanded by the development of user-friendly microscope systems that use digital imaging for data acquisition, analysis, and storage.

The principle behind in situ hybridization (and many other molecular techniques) is the ability of complementary single-stranded DNA sequences to specifically reanneal, forming double-stranded DNA (hybrid) molecules. The probe DNA molecules are enzymatically labeled with modified nucleotides. The hapten- or fluorescent-labeled DNA molecules then bind to chromosomes and cell nuclei at the site of specific (homologous) DNA sequences by in situ hybridization. In contrast to the hybridization of nucleic acids in solution, the target DNA sequences by in situ hybridization. In contrast to the hybridization of nucleic acids in solution, the target DNA sequences by in situ hybridization. In contrast to the hybridization of nucleic acids in solution, the target DNA sequences by in situ hybridization. Therefore, at the theoretical level, many aspects of in situ hybridization procedures still have a largely empirical basis. Briefly, probe DNA and target chromosomes are denatured and the resulting single-stranded DNA molecules are then allowed to reanneal. After various washing and detection steps, a specific fluorescence signal is visible at the chromosomal site of probe hybridization.

Overall, FISH is a surprisingly simple and robust technique which has applications in many different research areas, including clinical cytogenetics, gene mapping and genomics, evolution, and tumor biology. Although FISH methodology is used predominantly for the study of the human genome, FISH techniques have been successfully adapted for use in the study of a wide variety of genomes, from those of yeast to man. In this light, the following protocols may be useful not only for human cytogeneticists but for a wide variety of chromosome researchers.

2 EQUIPMENT FOR DIGITAL IMAGING MICROSCOPY

A typical FISH workstation consists of the following components.

1. A relatively simple upright epifluorescence microscope with objectives, epifluorescence filter sets, and excitation source. Switching between different fluorochromes is achieved by changing filter sets. In routine FISH work, cross-talk between blue, green, and red fluorochromes (i.e. 4',6-diamidino-2-phenylindole (DAPI), fluorescein isothiocyanate (FITC), and Cy3) imaged with their specific filter sets should be less than 10%. Longpass filters produce brighter single-fluor images but poorer spectral discrimination between fluorochromes. The most commonly used light source that will excite fluorescent dyes from the ultraviolet (UV) into the red region of the spectrum is the high-pressure mercury arc. The projection optics form a real image at the focal plane of the camera.

2. Thermoelectronically cooled charge-coupled device (CCD) cameras with medium format CCD chips are recommended for FISH imaging. A host computer is needed for camera control, image acquisition, image processing, image display, and storage of data. Digital imaging benefits from a very fast computer with 40–60 Mb of RAM (random access memory). Large image files require a hard disk capacity of about 2 GB and a back-up system.

3. Software packages for image acquisition, processing, and data analysis are available from different
companies, i.e. Applied Imaging, Leica Microsystems Imaging, Meta Systems, Oncor, PSI, Vysis, and others. Since FISH software packages can be quite costly and usually not all of the functions are needed in a routine laboratory, it is strongly recommended that software is tested in the lab using typical chromosome preparations and experimental conditions. Typically a series of images is taken through different filters. These gray-scale source images have to be merged and pseudo-colored. Sometimes the image background needs to be cleaned up and/or the specific signal needs to be enhanced. For gene mapping, it is very useful to convert DAPI fluorescence of a chromosome into a G-banding pattern for chromosome identification. Furthermore, it should be possible to measure the chromosomal location (fractional chromosome length) of FISH signals and to (manually) arrange chromosomes into a karyotype.

3 DNA PROBES

The various applications of FISH would not be possible without the general availability of DNA probes for specific chromosomes or chromosome regions of interest. Today a large number of different types of probes for human and other important model genomes are available, either commercially or from various genome resource centers and research laboratories. The choice depends mainly on the specific requirements of the experiments and on the laboratory expertise in molecular cytogenetics. For example, satellite DNAs are ideal probes for beginners, because they do not require suppression hybridization, and therefore are much easier to use than genomic probes containing interspersed repetitive elements. The efficiency of hybridization and the fluorescence at the hybridization site largely depend on the size of the target DNA sequences on the chromosome. Hybridization sites spanning several kilobases should be detectable without sophisticated equipment.

3.1 Satellite and Localized Repeat DNAs

Satellite DNA families are based on tandemly repeated monomers or higher-order repeating structures consisting of diverged monomers. Since satellite-DNA-containing chromosomal regions are not interspersed with other cross-hybridizing sequences, and usually span several hundred kilobases to several megabases, they are easily detected by FISH without suppression hybridization. This means that the prehybridization step (see standard FISH protocol in section 5) can be omitted. Chromosome-specific satellite DNAs or rRNA gene clusters produce very intense and compact signals in both metaphase and interphase cells (Figure 1d, g). One of the most thoroughly studied repetitive DNA families is α-satellite DNA, which is found at the centromeric regions of all human and primate chromosomes.5–7 Chromosome-specific α-satellite subsets have been described for the majority of human chromosomes and are widely used in routine cytogenetic laboratories, i.e. for aneuploidy studies.

3.2 Chromosome-specific DNA Libraries

DNA libraries represent complex mixtures of DNA sequences that are derived from a single chromosome type and, therefore, specifically paint the target chromosome by FISH (Figure 1c, e; Figure 2a). Whole-chromosome painting probes of high quality have been constructed from flow-sorted human and other mammalian chromosomes8–10 and by chromosome microdissection.11 In addition, microdissection has been used to generate region-specific DNA libraries.12

3.3 Region-specific Large-insert Clones

Large-insert probes, such as cosmids, λ phages, bacterial artificial chromosomes (BACs), P1-derived artificial chromosomes (PACs), and YACs, produce high-intensity site-specific FISH signals on 80–100% of the hybridized chromosomes and cell nuclei. Our lab has created a large set of (to date) 2000 YAC probes with approximately one YAC every 3–5 cM (centimorgan) spaced evenly over the entire human genome covering all human chromosome bands.13 These YACs have been well characterized by polymorphic genetic markers and FISH-mapped on human metaphase chromosomes. This standard set of cytogenetically and genetically anchored YACs allows the rapid integration of genetic and cytogenetic maps. It is an extremely flexible tool for use in a wide variety of FISH applications, such as the study of pathological and evolutionary chromosome rearrangements (Figure 1a–e; Figure 2b, c). Similar molecular cytogenetic resources have been generated for the mouse and other experimental animals.14,15 For most FISH experiments, purification of the clone insert is not necessary. Labeled vector sequences in the DNA probe do not hybridize appreciably to human chromosomes. Non-specifically formed (vector–chromosome) hybrid molecules are dissociated during the posthybridization washings (see section 5.3).

3.4 Total Genomic DNAs

In situ hybridization with total (genomic) nuclear DNA was first applied in plant cytogenetics for identifying parental chromosomes in interspecific plant hybrids and
Figure 1 Clinical cytogenetic applications of FISH: detection of structural and numerical chromosomal aberrations. (a) Triplication of subtelomeric sequences in the long arm of chromosome 1. The red yeast artificial chromosome (YAC) produces similar hybridization signals on both chromosomes. The green YAC produces three double-dot hybridization signals on the aberrant chromosome. (b) Hybridization of YACs specific for the subtelomeric regions on the short (green) and long (red) arms of chromosome 6, respectively. (c) Paracentric inversion on the X chromosome of a female patient. Both X's are painted with a chromosome-specific DNA library (green). The red YAC produces a single hybridization signal on the short arm of the normal X and a split signal on the long and short arms of the inverted X. (d) Balanced translocation between chromosomes 2 and 12. The green α-satellite probe hybridizes to the centromere of the normal chromosome 2 and the translocated chromosome der(2). The red YAC hybridizes to the proximal long arm of the normal chromosome 2 and to the translocated chromosome der(12). The hybridized probes flank the breakpoint on chromosome 2. (e) The same X inversion as seen in (c) during interphase. Note the split YAC hybridization signal in the upper X-chromosomal domain. (f) Asynchronous replication of subtelomeric sequences. The green 4qter YAC produces two hybridization doublets, indicating that the delineated homologous segments are fully replicated. The red 10qter YAC produces one unreplicated singlet and one replicated doublet hybridization signal, consistent with asynchronously replicating homologous chromosome regions. (g) Hybridization of five differentially labeled α-satellite DNAs specific for chromosomes 5, 6, 8, 20, and X on a normal female interphase nucleus.
following the introgression of alien chromosomes.\(^{16,17}\) More recently comparative hybridization of genomic tumor DNA versus normal reference DNA on normal human metaphase spreads has been used to assess chromosome gains and losses in tumor tissues.\(^{18}\)

### 3.5 cDNAs

Complementary DNAs (cDNAs) represent only the transcribed (exonic) sequences of genes and contain as little as several hundred base pairs (bps) of target sequence. The hybridization efficiency is low and depends on both cDNA size and intron/exon structure of the targeted gene. FISH mapping of cDNAs and small-insert (<1 kb) plasmid clones requires special expertise and/or digital imaging microscopy.

### 4 PROBE LABELING

Two major alternatives exist for fluorescent hybridization methods: direct and indirect. In the direct method, fluorescent reporter molecules are incorporated directly into the DNA probe. A wide variety of fluorescent deoxynucleotide triphosphates (dNTPs) can be used for direct labeling, i.e. FITC-, Texas Red-, Rhodamine-, Cy3-dUTP, and many more. Since the probe–target DNA hybrids resulting from in situ hybridization are immediately visible under the microscope, direct methods are very fast. They offer other advantages, such as low background fluorescence and increased possibilities for multicolor analysis. On the other hand fluorescent probes are prone to photobleaching during preparation and hybridization. In the indirect method, hapten reporter molecules, i.e. biotin- or digoxigenin-dUTP, which are introduced into the DNA probe, are detected by affinity cytochemistry after the hybridization reaction. Fluorescent (strept)avidin molecules bind specifically to biotin-labeled probe–target hybrids. Fluorescent antidi-goxigenin antibodies are used to detect digoxigenated probes. The fluorescence signals of indirectly labeled probes may be up to ten times brighter than those produced by direct methods. In addition, small hapten molecules such as biotin are more efficiently incorporated into DNA than most fluorescent dNTPs. Thus, indirect labeling may be preferable for most FISH applications. Haptenized and, to a lesser extent, fluorescent probes can be stored at \(-20^\circ\)C for many years without compromising performance.

Different enzymatic labeling procedures can be used to introduce modified dNTPs into DNA probes, i.e. nick translation, random priming, and polymerase chain reaction (PCR). Nick translation\(^{19}\) is recommended for labeling double-stranded DNA molecules because large amounts of DNA can be labeled and most FISH experiments require high probe concentrations. Random priming\(^{20}\) has the advantage that small amounts of DNA and single-stranded probes can be efficiently labeled. PCR is a very convenient and fast method for labeling PCR-amplifiable large-insert probes and DNA libraries.

#### 4.1 Nick Translation

The DNA template can be supercoiled or linear. After nicking the DNA with DNase I, the 5'–3' exonuclease activity of DNA polymerase removes nucleotides and the DNA polymerase activity replaces the excised nucleotides with dNTPs from the reaction mixture, including the labeled nucleotide. The procedures for incorporating biotin, digoxigenin, or fluorochromes are nearly identical. The kinetics of the reaction reaches an optimum after 30–60 min. The final size of the nick-translated probe DNA fragments is very important. Labeled probe sequences which are larger than 500 bp have difficulty penetrating the specimen and a tendency...
Figure 2 Comparative genome mapping by FISH. (a) Hybridization of painting probes specific for human chromosome 5 (green) and 17 (red) on human (HSA) and gorilla (GGO) metaphase spreads. Note the evolutionary rearrangement (translocation) involving the gorilla homologs of HSA 5 and 17. (b) Hybridization of a subtelomeric YAC from the long arm of human chromosome 3 on the Old World monkey Presbytis cristata (PCR). Note the split hybridization signal on the monkey homolog of HSA 3. The hybridized YAC spans an evolutionary chromosome breakpoint. (c) Hybridization of the same YAC on great ape and monkey homologs of HSA 3. Orangutans (PPY) and humans show the same hybridization patterns. In gorilla and Old World monkey the YAC delineates paracentric inversions involving the same distal but different proximal breakpoints. This indicates the occurrence of convergent chromosomal mutations. Insets show converted DAPI images (G bands).
to stick nonspecifically to both the glass and the cellular material, resulting in high background which obscures the signal. Sequences shorter than 100 bp do not hybridize efficiently under routine conditions of stringency.

Mix on ice, in a microcentrifuge tube:

DNA (in liquid format) 1 µg
10 × nick-translation buffer (see Appendix 1) 5 µL
0.1 M β-mercaptoethanol (BME) (see Appendix 1) 5 µL
10 × cold dNTP solution (0.5 mM each of dATP, dCTP, dGTP) 5 µL
10 × 1:3 labeled dUTP/cold dTTP solution (0.125 mM labeled dUTP, i.e. biotin-16-dUTP or digoxigenin-11-dUTP, and 0.375 mM dTTP) 5 µL

A labeling density of one modified nucleotide at approximately every 20–25th position in the nick-translated DNA is optimal for most FISH experiments.

DNase I 5 µL (DNase stock with an activity of 10 U µL⁻¹ is diluted 1:3000–1:4000 with ddH₂O (double-distilled water))

Optimal DNase concentration must be determined by titration, as the size distribution of the probe depends on the amount of enzyme added. Each new stock of DNase I should be tested to determine the appropriate working concentration.

DNA polymerase I 1.3 µL
(5 U µL⁻¹)

ddH₂O Add as needed to achieve final reaction volume of 50 µL

If larger amounts of DNA (up to 5 µg) need to be labeled, the reaction volumes can be scaled up to 250 µL.

Incubate the reaction mixture for 2 h at 15 °C. The time of incubation should not be shortened; at least 2 h are necessary for optimal incorporation, as the initial incorporation rate of modified nucleotides is less than that of unsubstituted dNTP.

Check the size of the nick-translated DNA fragments on a 1.5% agarose gel, along with suitable size markers (0.1–1 kb range). If the DNA fragments are still too large, add a second aliquot of DNase (optional) and incubate for another 30–60 min at 15 °C.

When the majority of the fragments are between 100 bp and 500 bp in size, terminate the reaction by adding stop buffer (1.25 µL 0.5 M EDTA (ethylenediamine tetraacetic acid) and 0.5 µL 10% SDS (sodium dodecyl sulfate) (see Appendix 1) to the 50 µL of nick-translation mixture. Heat tube to 68 °C for 10 min.

For most types of probes, i.e. satellite DNAs, DNA libraries or large-insert clones, purification of the labeled probe DNA is not necessary. Simple ethanol precipitation is sufficient. For small single-copy DNA probes, purification by centrifugation through Sephadex G-50 or commercially available columns is recommended to remove unincorporated haptenized or fluorescent nucleotides.

4.2 Polymerase Chain Reaction

Degenerate oligonucleotide primed (DOP)²¹ and inter-Alu²² PCR are widely used to amplify complex DNA probes from large-insert clones, i.e. PACs and YACs, and flow-sorted or microdissected DNA libraries. Alu PCR amplifies only sequences located between Alu repeats in the human insert, whereas DOP PCR amplifies vector (bacterial or yeast) sequences along with the entire insert. However, since DOP PCR products are much more complex than Alu PCR products, they usually generate better FISH signals. PCR-generated probes can be efficiently labeled by re-amplification of the DOP or Alu PCR product, in reactions where dTTP is partially replaced by modified dUTP. Since optimal PCR conditions are largely dependent on the DNA template and primer(s), the DOP PCR labeling protocol described here is, by necessity, generalized.

Mix on ice, in a centrifuge tube:

Template DNA (in liquid format) 200–400 ng
10 × Taq polymerase buffer (see Appendix 1) 5 µL
25 mM MgCl₂ 4 µL
20 pM µL⁻¹ DOP primer 20 µL
(5’-CGC ACT CGA GN MnN NAT GTG G-3’)
2 mM dATP 3.75 µL
2 mM dCTP 3.75 µL
2 mM dGTP 3.75 µL
2 mM dTTP 1.25 µL
1 mM biotin-16-dUTP (or other labeled dUTP) 0.5 µL
Taq polymerase 0.5 µL
ddH₂O Add as needed to achieve final reaction volume of 50 µL

After an initial denaturation at 94 °C for 1 min, 30 cycles are carried out with denaturation at 94 °C for 1 min, annealing at 56 °C for 1.5 min, and extension at 72 °C for 2 min followed by incubation at 72 °C for 10 min.
5 IN SITU SUPPRESSION HYBRIDIZATION
(STANDARD FLUORESCENCE IN SITU
HYBRIDIZATION PROTOCOL)

Ubiquitously repeated sequences, i.e. of the Alu and L1 families, occur approximately 900,000 and 100,000 times in the human genome respectively.\textsuperscript{(23)} Since interspersed repeats are present at least once in every 5 kb of genomic DNA, complex DNA libraries, large-insert clones, and most other DNA probes contain a significant number of repetitive elements that can cross-hybridize with closely related repeats throughout the entire genome. Consequently, these probes will not only hybridize to their specific target DNA sequences but to all chromosomes, yielding ambiguous FISH signals. To prevent such unspecific hybridization, repetitive DNA sequences in the probe DNA are blocked by prehybridization with unlabeled total genomic DNA or repetitive Cot-1 DNA.\textsuperscript{(24–26)} The fast reassociating (Cot-1) fractions of genomic DNA probes reanneal under the appropriate (pre)hybridization conditions, and thus mainly single-copy DNA sequences in the hybridization mixture remain single-stranded and can hybridize to their target sequences on chromosomes. The following is a detailed protocol for suppression hybridization that has been optimized for the fluorescent detection of single-copy DNA sequences.

5.1 Hybridization Mixture

Nick-translated DNA probes have a final concentration of approximately 20 ng µL\(^{-1}\) (in nick translation buffer), PCR-labeled probes one of approximately 100 ng µL\(^{-1}\) (in Taq polymerase buffer). First, differentially labeled probes which are to be hybridized on the same specimen are precipitated together with an approximately 50-fold excess of Cot-1 competitor DNA (Gibco BRL) or a 500-fold excess of fragmented (100–500 bp) total genomic DNA, and a 50-fold excess of fragmented salmon sperm DNA (see Appendix 1) which is used as a carrier. The optimal DNA concentrations in the hybridization mixture (30 µL for a whole slide) depend mainly on the probe types. For large-insert PAC and YAC clones, 10–20 ng µL\(^{-1}\) in the hybridization mixture (or 300–600 ng per slide) are recommended. For small-insert plasmid clones and cDNAs, higher probe DNA concentrations of 20–50 ng µL\(^{-1}\) may be superior. For very complex (painting) probes, such as chromosome- or arm-specific DNA libraries, 5–10 ng µL\(^{-1}\) in the hybridization mixture (or 150–300 ng per slide) usually yield good results. The probe concentration in the hybridization mixture affects the rate at which the first few base pairs are formed (nucleation reaction). The adjacent base pairs are formed afterwards. Since the nucleation reaction is the rate-limiting step in hybridization, the higher the concentration of the probe, the higher the reannealing rate.

As a rule, the higher the proportion of repetitive elements present in the probe DNA, the more the competitor DNA that is needed. Probes containing mainly interspersed repeats and only few single-copy sequences are difficult to hybridize and yield inferior FISH signals. As might be expected, if too little competitor DNA is added, background signals from the interspersed repetitive elements will not be effectively suppressed. Vice versa, the addition of too much competitor DNA will reduce the signal intensity as well as the background.

In the following example, a YAC and a chromosome-specific DNA library will be hybridized together on the same slide.

Precipitate the DNA as usual with 1/20 volume 3 M NaAcetate (see Appendix 1) and 2 volumes 100% EtOH (p.a.) in a microcentrifuge tube. Mix well and keep the tube for at least 30 min at \(-70^\circ C\) or overnight at \(-20^\circ C\). Spin for 30 min at 15,000 rpm at 4°C. Discard the EtOH and dry the pellet in a vacuum system or a 37°C heating block.

Add 15 µL of deionized formamide (see Appendix 1) and shake at 37°C for at least 15 min to resuspend the probe DNA. Then add an equal volume of 2 x hybridization mixture (20% dextran sulfate, 4 x SSC (standard saline citrate)) (see Appendix 1) and shake vigorously for at least 15 min. Dextran sulfate is very hydrophilic. The consequence is that macromolecules such as DNA have no access to the hydrating water, which leads to an apparent increase in probe concentration and consequently higher hybridization rates.

Routine conditions of stringency are 50% formamide, 10% dextran sulfate, 2 x SSC in the hybridization mixture. Occasionally, stringency conditions may need to be increased (e.g. for highly repetitive satellite DNAs or if a single-copy probe also cross-hybridizes weakly to a second site) or decreased (e.g. if trying to hybridize with a very short oligonucleotide probe or with a complex probe from a related species). Hybridization stringency can be increased by increasing the incubation temperature or the formamide concentration, or by decreasing the salt (SSC)
concentration in the hybridization mixture. Usually, stringency is increased by using 60–70% formamide in the hybridization mixture, or decreased by using only 20–30% formamide.

Denature the hybridization mixture (containing the probe DNA) at 80°C for 10 min. Centrifuge the probes for 2–5 s in order to pellet the condensed water.

To allow reannealing of repetitive DNA fractions, incubate the tube with the denatured competitor and probe DNA at 37°C for at least 15 min (but not longer than 1 h).

Place the preannealed DNA probe (30 µL) on the denatured slide and cover with a coverslip. Seal the edges with rubber cement and incubate overnight (or longer) at 37°C in a moist chamber.

5.2 Slide Preparation

The quality of the chromosome preparations is a very critical parameter for the efficiency of FISH. Metaphases can be prepared from any (exponentially) growing cell culture, i.e., short-term blood cultures, bone marrow, fibroblasts, lymphoblastoid cell lines, and tumor cells. The most widely used procedure for the preparation of high-quality chromosomes involves phytohemagglutinin stimulation of T lymphocytes of human peripheral blood in culture and metaphase arrest by adding the spindle poison colcemid shortly before harvesting. Harvested cells are swollen in hypotonic solution (50 mM KCl at 37°C for 5–10 min) and fixed in a 3:1 mixture of ice-cold methanol–acetic acid. Chromosome suspensions can be stored at −20°C for several months without compromising performance.

To prepare slides, put one drop of chromosome suspension on a very clean glass slide. Ambient temperature and humidity influence how quickly the fixative dries on the slide. Slides which dry too quickly have very low contrast and the chromosomes have a tendency to come off the slide. Slides which dry too slowly may exhibit poor morphology after denaturation. Chromosome preparations for FISH should be between one day and one month old. Extra slides can be stored in a desiccating box.

Incubate the slides with pepsin for 10 min (but not much longer) at 37°C in 0.05% (w/v) pepsin powder in 0.01 M HCl. Wash slides 2 × 5 min in 1 × PBS (phosphate-buffered saline) (see Appendix 1) and then 2 × 5 min in 1 × PBS containing 50 mM MgCl₂. Fix slides with 1% formaldehyde, 1 × PBS, 50 mM MgCl₂ for 10–60 min at room temperature. Wash the slides thoroughly in PBS. Pepsin and other proteases (i.e., proteinase K or pronase) increase accessibility by digesting chromosomal proteins that package the target DNA. Since metaphases and nuclei have the tendency to come off the slides after prolonged protease treatment, refixation of the slides with formaldehyde is recommended.

Dehydrate slides in an ethanol series (70%, 85%, 100%) for 5 min each and air-dry. Place 200 µL of denaturation solution, consisting of 70% deionized formamide and 2 × SSC (see Appendix 1), on each slide and cover with a coverslip. Place in a 90°C oven for approximately 60 s. Shake off coverslip and put slide immediately in ice-cold 70% ethanol. Dehydrate again in an ice-cold ethanol series (70%, 85%, 100%). After air-drying, the slides are ready for in situ hybridization.

Alternatively, chromosomes may be denatured in a water bath at 70°C by immersing the slide for 2–5 min in a Coplin jar with 70% formamide, 2 × SSC. This may be more accurate and easier to standardize than the procedure described above, but it also creates more waste. Formamide is a proven carcinogen and teratogen. Denaturation of chromosomal target DNA can also be achieved with extremes of alkaline pH; however, heat (formamide) denaturations have become popular because of their experimental reproducibility and greater effectiveness.

Poorly fixed chromosomes may over-denature, resulting in a hollow, puffy appearance under the phase contrast microscope, and/or come off the slide during denaturation in formamide. Inferior grade formamide may also destroy much of the chromosomal morphology. Denaturation inevitably leads to loss of morphology, so in practice a compromise must be found between hybridization signal and chromosome morphology. Variations in time and temperature should be evaluated to find the best conditions for denaturation.

5.3 Hybridization and Signal Detection

Pipette 30 µL of denatured and pre-annealed probe mixture on the prewarmed slide (15 µL for half a slide). Cover the slide with a coverslip, being careful not to trap air bubbles, and seal the edges with rubber cement.

Hybridize overnight in a moist chamber at 37°C. Longer hybridization times (2–7 days) may be required for probes which do not show 100% sequence identity with the chromosomal target.

Wash the slides for 3 × 5 min at 42°C in 50% formamide, 2 × SSC (see Appendix 1) and then 2 × 5 min at 60°C in 0.1 × SSC. To lower the stringency, increase the salt concentration (i.e., to 0.5–2 × SSC) of the last two
washes. To increase the stringency, use 65% formamide, 2 × SSC for the first three washes. However, hybridization rather than stringent washing is recommended. The washing solutions are pre-warmed in different water baths. The Coplin jar with slides and pre-warmed washing solution is agitated on a platform shaker.

The probe DNA hybridizes not only to the target DNA but also nonspecifically to sequences which bear partial homology to the probe sequence. Since such nonspecific hybrids are less stable than perfectly matched DNA hybrids, they can be dissociated by posthybridization washes of various stringencies.

Directly labeled probes can be viewed immediately after the posthybridization washes. Secondary incubations and washes are required for the visualization of haptenated DNA probes. Prior to incubation with secondary reagents, slides should be blocked by treating with 5% bovine serum albumin (BSA) in 4 × SSC, 0.1% Tween 20. Incubate slides in a Coplin jar with fresh blocking solution (see Appendix 1) for at least 30 min at 37 °C. Blocking prevents unspecific antibody binding and reduces background.

Dilute fluorescent (strept)avidin and anti-digoxigenin antibodies, i.e. FITC-avidin and Cy3-conjugated anti-digoxigenin, 1:800 and 1:200, respectively (or according to recommendations of the supplier) in 1% BSA, 0.1% Tween 20, 4 × SSC (see Appendix 1). Cover the slides with 200 µL of detection solution and a coverslip. Incubate in a moist chamber in the dark at 37 °C for 30 min.

Shake off the coverslips and wash the slides 3 × 5 min in a Coplin jar with 0.1% Tween 20, 4 × SSC (see Appendix 1) at 42 °C.

To visualize chromosomes and cell nuclei, counterstain the slides for 1–2 min with 1 µg mL⁻¹ DAPI in 2 × SSC. Wash the slides thoroughly with distilled water, air-dry and then mount them with antifade mounting medium (see Appendix 1). 1,4-Diazobicyclo[2.2.2]octane (DABCO) retards fading of the fluorescence after exposure of the slides to fluorescence light.

Large-insert clones and DNA libraries should produce specific fluorescence signals, which are clearly visible by eye through the microscope. Small probes (<5 kb) and cDNAs may require immunological signal amplification to be seen by eye. The fluorescence of (strept)avidin–biotin complexes can be enhanced by using biotinylated goat anti-avidin antibody followed by another incubation with fluorescent (strept)avidin. This “sandwich technique” for signal amplification of biotinylated probes can be repeated several times. (28) Digoxigenated DNA probes binding fluorescent mouse anti-digoxigenin antibody can be amplified with a second layer of fluorescent rabbit anti-mouse antibodies and, if necessary, with a third layer of fluorescent goat anti-rabbit antibodies. FISH signal intensities can be even more dramatically enhanced by the tyramide method. (29) Peroxidase-conjugated (strept)avidin or anti-digoxigenin antibody is applied as a first layer. In a second step, this peroxidase uses fluorescent or biotinylated tyramide as a substrate to deposit many fluorochrome or biotin molecules in the immediate vicinity of the in situ bound enzyme. These can be evaluated either directly or after a third incubation with fluorochrome-labeled (strept)avidin. As a general rule, every amplification level not only enhances the signal, but also the background intensity. Because of the high sensitivity of digital cameras, use of electronic image enhancement is arguably preferred over immunocytochemical signal amplification.

Proper chromosome identification requires the simultaneous observation of chromosome bands and hybridization signals. A large number of widely different fluorescent banding procedures have been proposed, including FISH of interspersed Alu elements, which are enriched in R bands; (30) saline heat treatment followed by acridine orange staining; (31) and various counterstain-enhanced banding methods, i.e. actinomycin/DAPI staining for G bands or distamycin A/chromomycin A3 for R bands. (32) In general, the resulting chromosome banding patterns are just sufficient to identify chromosomes and to map probes at a low resolution (250–300 band level). Fluorescent replication banding of BrdU-substituted chromosomes tends to produce a more accurate banding after hybridization. (33)

Specialized FISH software allows the conversion of the plain DAPI fluorescence of a chromosome into a G-like banding pattern (Figure 2c; Figure 3c). In addition, the cytogenetic location of a hybridization signal can be expressed as the fractional length (FLpter) of the total chromosome relative to the short-arm telomere. (34) Many FISH programs infer the cytogenetic band location from the FLpter measurement. In this context it is important to note that varying degrees of chromosome condensation can lead to discordances between FLpter values and band assignments. Nevertheless, both digital banding and FLpter measurements are very straightforward and now used in most laboratories.

6 MULTICOLOR FLUORESCENCE IN SITU HYBRIDIZATION

One of the major advantages of FISH is the possibility of simultaneously detecting multiple DNA targets on the same metaphase in different colors. Using standard experimental conditions and FISH workstations, one probe may be detected with a green fluorescent dye, a second probe with a red dye, while the chromosomes...
are counterstained in blue with DAPI. The three different colors are discriminated with the aid of specific filter sets. In the past few years, an increasing number of spectrally resolvable fluorochromes, ranging from the visible blue to the near infrared, has been developed for the fluorescent detection of DNA probes in multicolor FISH experiments. By combinatorial probe labeling, many more DNA targets can be discriminated than the number of distinguishable fluorochromes. Combinatorial labeling involves the introduction of two or more fluorochromes into a single probe in approximately equal amounts. Different probes are characterized by different combinations of fluorochromes. The maximum number of useful Boolean combinations of $n$ fluors is $2^n - 1$. The 31 possible combinations for five fluorochromes allow one to uniquely identify all 24 human chromosome types.

Figure 3 Multicolor FISH analysis of a tumor metaphase spread. (a) Spectral karyotype. Note the enlarged chromosome 2 (large arrow) and the additional chromosome 2 material (small arrow) on the long-arm tip of chromosome 16. (b) Spectral image and (c) converted DAPI image of the respective metaphase spread. Despite inferior tumor metaphase quality, the rearranged chromosomes are easily identified.
There are two strategies for analyzing combinatorial multicolor FISH images. The multiplex fluorescence in situ hybridization (M-FISH) procedure is based on highly specific epifluorescence filter sets that have very narrow bandwidths, compared with standard filters, and, therefore, give a high degree of discrimination between all possible fluor combinations. Images are acquired separately for each of the five fluorochromes and for DAPI counterstaining, then are overlaid, generating a composite image. Specialized software is used to pseudocolor each chromosome according to its fluorochrome composition. In contrast, spectral karyotype analysis (SKY) is significantly different from conventional epifluorescence microscopy and does not rely on fluorochrome-specific optical filters. It combines optical microscopy, Fourier spectroscopy, and CCD imaging. Discrimination of multiple fluorochromes is achieved by measuring a discrete fluorescence emission spectrum (representing a sequence of intensities at many different wavelengths) simultaneously at all image points after a single exposure. A filter set with broad emission bands allows the simultaneous excitement of all dyes and measurement of their emission spectra. Specialized software then classifies each chromosome, by assigning the same pseudocolor to all pixels with the same emission spectrum (Figure 3).

PCR-amplifiable DNA libraries from microdissected or flow-sorted chromosomes are used as a starting material. Table 1 shows a combinatorial labeling scheme for 24-color FISH. Spectrum Orange, Texas Red, and Rhodamine are directly incorporated by PCR. Cy5-avidin and Cy5.5-conjugated antibodies are used as secondary reagents to detect biotinylated and digoxigenated probes. For each probe, one to four separate PCR labeling reactions are necessary, each with a fluorescent, biotinylated and Cy5.5-conjugated antibodies are used as secondary.

After the pre-annealing step, put the probe mixture on the denatured chromosome preparation. Hybridization should be done for several days (up to one week) at 37°C in a moist chamber in the dark.

Posthybridization washes should be done, using standard conditions of stringency (see section 5.3). Then incubate the slides with Cy5-avidin and mouse anti-digoxigenin antibody, diluted 1:500 and 1:200, respectively, in 1% BSA, 0.1% Tween, 4 × SSC. After washing the slides 3 × 5 min with 0.1% Tween, 4 × SSC, incubate slides with Cy5.5-conjugated anti-mouse IgG, diluted 1:200 with detection buffer (see Appendix 1). All incubation and washing steps must be performed in the dark. Finally, counterstain the slides with DAPI and mount them.

Spectral analysis requires a SpectraCube system (Applied Spectral Imaging). The imaging system is attached to an epifluorescence microscope. It consists of an optical head with a Sagnac common path interferometer. The interferogram of each pixel is analyzed by Fourier transformation, to create a spectrum. This spectrum is imaged with a CCD camera. A spectral-based classification algorithm identifies the multiple different spectra in the acquired image and highlights them in RGB (red/green/blue) classification colors. By computer classification of spectra, the spectrally overlapping (combinatorially labeled) 24 DNA libraries can be resolved.
and the entire genome can be analyzed simultaneously on the basis of the differential display of all human chromosomes.

Multicolor karyotyping is a very powerful screening method for complex interchromosomal rearrangements, i.e. in tumor cells (Figure 3). It can decipher extensively rearranged karyotypes that cannot be fully characterized by classical chromosome banding or conventional FISH. The limit of sensitivity for karyotype analysis with combinatorial probe labeling and currently available M-FISH or SKY systems is in the order of several megabases and, thus, lower than that with standard (three-color) FISH. An alternative approach to increase the number of detectable chromosomal targets beyond the number of spectrally resolvable fluorochromes is ratio labeling. For example, all 24 human chromosomes can be discriminated by a combination of only four fluorochromes at different ratios.  

7 COMPARATIVE GENOMIC HYBRIDIZATION

CGH is a method to screen a genome for DNA-sequence copy-number variation.  

Tester DNA, isolated from a tumor or a patient, and normal (human) reference DNA are labeled with different fluorochromes, i.e. FITC for the tester DNA and Cy3 for the reference DNA, and hybridized together on normal metaphase spreads under suppression conditions. Hybridization of tester DNA from a chromosomally balanced genome results in a more or less uniform staining of the target chromosomes with both colors. Regions of gain and loss of DNA sequences in a tumor change the relative amounts of tester and reference DNA bound at the respective chromosomal loci and can be identified by measuring the ratio of intensities of the two fluorochromes (Figure 4). Amplifications and deletions in the test sample should be visible as higher and lower green fluorescence intensity relative to the red fluorescence intensity of the reference DNA. Large chromosomal imbalances, i.e. loss or gain of an entire chromosome, lead to marked differences in the hybridization profile of the target chromosome on the hybridized normal metaphase spread and should be visible by eye through the microscope. Specialized CGH software, which integrates the green-to-red fluorescence intensities and calculates the ratio along the hybridized chromosomes (Figure 4b), allows the detection of smaller regional changes involving gain or loss of one copy of approximately 10 Mb DNA. Of course, high-level amplifications, i.e. of certain oncogenes, yield a much higher DNA resolution of CGH. Most importantly, in contrast to classical tumor cytogenetics, CGH does not require tumor metaphase spreads. Karyotype analysis in solid and many other tumor types has been hampered by low mitotic index and poor metaphase quality. A single CGH experiment provides comprehensive information on genetic imbalances. However, it cannot detect balanced chromosome rearrangements such as translocations and inversions. In this light, multicolor FISH and CGH are complementary techniques.

If possible, total genomic tumor and reference DNA should be used for CGH experiments. High-molecular-weight DNA is prepared according to standard procedures. One milligram of tissue yields approximately one microgram of genomic DNA. When only small amounts of fresh tumor tissue or archival tumor material are available, a DNA template is generated by DOP PCR amplification.

Tumor DNA is labeled by standard nick translation with biotin and detected with FITC-avidin. Reference DNA is labeled with digoxigenin and detected with Cy3-conjugated anti-digoxigenin antibody. Direct labeling is also possible. The optimum probe-fragment-size distribution after nick translation ranges from about 500 bp to 2000 bp. For CGH, the probe DNA fragments should be somewhat larger than for standard FISH experiments (200–500 bp) in order to obtain uniform and intense hybridization on chromosomes.

Samples (100 ng) of each biotinylated tumor and digoxigenated reference DNA are combined with 50–100 µg unlabeled Cot-1 DNA. The precipitated probe DNA is resuspended in 50% formamide, 10% dextran sulfate, 2 × SSC.

Following denaturation of probe and slides, comparative hybridization is performed for 2–3 days at 37°C in a moist chamber. The slides are washed and probes detected with secondary reagents (see section 5.3). The hybridization profiles are evaluated by specialized CGH software.

8 (ULTRA) HIGH-RESOLUTION FLUORESCENCE IN SITU HYBRIDIZATION

Standard FISH techniques are capable of resolving sequences separated by two or more megabases on metaphase chromosomes. Hybridization on less condensed interphase nuclei further increases the resolution to around 100 kb. The average interphase distance between different probe signals correlates with physical distances up to 1–2 Mb. Interphase mapping allows the order and relative proximity of sequences which are closely juxtaposed on the same chromosomal region, and therefore cannot be resolved on metaphase chromosomes, to be determined. Interphase
Figure 4 CGH. (a) Schematic representation of the CGH approach. Amplification of a DNA segment (in the proximal long arm) enhances the green-to-red fluorescence ratio of tumor DNA versus reference DNA on the respective chromosome and is shown in black. Conversely, deletion of the distal long arm in the tumor decreases the green-to-red fluorescence ratio of the target region and is shown in white on the reference chromosome. The mean ratio (thick line) plus/minus one standard deviation (thin lines) are shown for the entire chromosome from pter to qter. (b) Copy-number karyotype of a patient with constitutional chromosome aberration. The baseline value (1) representing the mean green-to-red ratio for the entire metaphase is shown in a solid line and ratios of 0.75 (loss bar) and 1.25 (gain bar) as dotted lines. Based on this analysis, the distal long arm of chromosome 4 (arrow) is over-represented in the patient. The X and Y ratios reflect the fact that DNA from a female patient was compared with a male reference DNA. The ratio data of regions that contain mainly repeat DNAs and may exhibit large copy-number polymorphisms are unreliable and, therefore, excluded from the analysis (horizontal gray bars). Hybridization signals in these regions are partially suppressed by Cot-1 DNA.

FISH has also proved valuable for determining replication order and timing of specific DNA sequences. Replicated DNA segments consisting of two sister chromatids appear as doublet hybridization signals during interphase, whereas unreplicated chromosomal segments with one chromatid give only single hybridization dots (Figure 1f). Most sequences have a defined time zone of replication within the cell cycle and replicate in a fairly
synchronous manner. Asynchronous DNA replication, which generates one doublet and one singlet hybridization signal on homologous interphase chromosomes, defines regions containing imprinted genes or repeat DNA families.

The general usefulness of interphase mapping is greatly hampered by the three-dimensional organization of chromatin in the cell nucleus. The data become more difficult or even impossible to analyze when the distance between markers is larger than several megabases. Based on the observation that less condensed interphase chromatin provides greater DNA resolution than metaphase chromosomes, different strategies have been developed to push the limits of resolution of FISH further by artificially decondensing chromatin. Briefly, the cells are lysed with high salt and/or detergent and the chromatin is spread across the surface of a glass slide either by gravity (tilting the slide) or by mechanical spreading. This can cause complete detachment of the DNA loops from the nuclear matrix, producing highly elongated chromatin fibers. The finest level of DNA resolution of the various fiber FISH protocols is 1–10 kb, thus closing the gap between (molecular) cytogenetic and molecular physical mapping techniques. Alternatively, high-molecular-weight DNA molecules in solution can be stretched on glass surfaces by molecular combing.

8.1 Fiber Fluorescence In Situ Hybridization

The following protocol describes the preparation of DNA fibers from agarose-embedded cells. This technique can be adapted in most laboratories, producing suitable targets for high-resolution mapping.

To improve retention of DNA fibers on slides, the slides are coated with poly-L-lysine as follows. Put slides through 0.2 M HCl, ddH₂O, and acetone for 30 s in each solution, then allow to air-dry at room temperature. Place the clean slides in 0.15% gelatin, 0.03% sodium azide solution for 5 min at room temperature, then rinse for 30 s with ddH₂O and air-dry at room temperature overnight. Use molecular biology grade gelatin and filter the solution to get rid of any gelatin not completely in solution.

Place slides in 0.02% poly-L-lysine for 10 min at room temperature, rinse for 30 s with ddH₂O and air-dry for 1 h. Then repeat poly-L-lysine incubation and ddH₂O rinse and dry overnight at room temperature. Slides stored at 4°C can be kept for months before use.

Most cell types can be used to prepare blocks for fiber FISH. Most commonly used are fibroblasts or peripheral blood lymphocytes. Collect, wash, and resuspend cells in 1 × PBS (see Appendix 1) to a concentration of 2 × 10⁶ cells per 100 µL. Warm this cell suspension slightly at 37°C. Have ready 1.9% low-melt agarose kept at 50°C. Mix melted agarose and cell suspension 1:1 and pipette into molds (blocks 100 µL or less) and chill for 30 min at 4°C. Final cell concentration in the blocks is 10⁶ cells in 100 µL.

Incubate blocks in a solution of 2 mg mL⁻¹ proteinase K, 0.5 M EDTA, pH 8.0, 1% n-lauroylsarcosine. Use at least 1 mL of this solution per 100-µL block. Incubate for 48–72 h at 50°C (with gentle agitation, if possible).

Leaving the blocks in the proteinase K solution, chill them for 30 min at 4°C to firm up the gel fragments, then transfer them into TE (10 mM Tris–HCl, pH 7.5, 1 mM EDTA) buffer (see Appendix 1), and wash for two days at room temperature, changing the TE several times over this time period. Blocks can be stored in 0.5 M EDTA at 4°C for months. Dialyse blocks stored in EDTA with several changes of TE before using for fibers.

For fiber formation, place approximately 10 µL of block on one end of a poly-L-lysine coated slide. Pipette onto the block around 40 µL of ddH₂O. Preheat the microwave oven to get the rotating glass plate very hot, by running empty for 5 min. One at a time, place a slide, with agarose and ddH₂O as described above, into the microwave with the slide near the outer edge of the rotating plate, and microwave at full power for 20–40 s.

Using a plain glass slide, spread the melted gel down the slide. Be sure that the agarose is completely melted. The angle of pulling should be low (20° or so) and the plain slide should be pulled with mild pressure. Ideally, the fluid should boil a bit as it gets pulled down the slide and the slide should appear dry immediately after pulling, i.e. extending the fibers. Allow slides to dry for about 1 h at room temperature.

Denature by placing the slides in a Coplin jar containing 100% formamide, 2 × SSC at 74°C for 4 min. This step is likely to remove quite a bit of the agarose. Put through an ethanol series (70%, 90%, 100%) at −20°C and then allow to air-dry. As soon as the slides are dry, they are ready for probe application and hybridization. Make the fibers the same day as the hybridization will be done.

Following probe hybridization for 1–3 days, wash slides for 3 × 5 min at 42°C in 50% formamide, 2 × SSC and then 2 × 5 min at 42°C in 0.5 × SSC. Immunocytochemical detection should be performed according to standard procedures.

The distance for fiber FISH mapping is 5–500 kb. Cosmids of 30–40 kb length produce a string of fluorescent signals up to several dozen micrometers long. YAC probes produce very elongated straight signals on a certain percentage of fibers. The longer the hybridized YAC, the more likely it is that its sequence may be disrupted during fiber preparation. It is important to note...
that the fibers onto which clones are mapped are condensed to varying degrees and, therefore, a larger number of fibers (at least 20) should be analyzed for quantitative measurements.

Fiber FISH techniques can be used to map clones, i.e. cDNAs or cosmids, with a few kilobases resolution on individual straightened DNA molecules. It allows one to order probes relative to each other, to orient probes within a contig, and to determine the degree of overlap or gap size between different probes (Figure 5).

**8.2 Molecular Combing**

Molecular combing is a process in which a solution of DNA target molecules is placed in parallel orientation on a flat glass surface. In the most simple method, a drop of DNA solution is placed on a silanized coverslip and covered with another untreated coverslip, forcing the drop to spread. DNA molecules bind to the vinyl end groups (\(-\text{CH}==\text{CH}_2\)) of the silanized glass surface by their extremities only, presumably because of the
presence of a free protonated phosphate at the 5′-end of DNA molecules. The receding meniscus of the air–water interface during evaporation of the solution exerts a force on the DNA, resulting in a more or less uniform extension of the attached DNA molecules. The highest density of linearized DNA molecules and constant stretching are achieved by using a DNA combing apparatus (Adil Instruments). Silanized coverslips are dipped into a Teflon® reservoir with buffered DNA solution, resulting in random binding of the DNA molecules at one end (usually the 5′-end) or occasionally at both ends to the glass surface. When the slide is pulled out of the DNA solution by a mechanical device, the hydrodynamic action of the receding meniscus straightens the DNA molecules. Due to the silanized surface, the DNA molecules dry immediately as the coverslip comes out of the solution, permanently fixing them to the coverslip surface. A major advantage of molecular combing is that DNA molecules are aligned in a single direction and homogeneously stretched (approximately 2 kb m−1). Similarly to fiber FISH, most combed molecules are longer than several hundred kilobases and occasionally as long as 1 Mb.

Standard agarose blocks (see section 8.1) containing YAC DNA or total human genomic DNA are used for the preparation of DNA solution. The blocks will contain approximately 10⁷ yeast cells, equivalent to 1 µg yeast DNA, or 10⁶ diploid human cells, equivalent to 6.6 µg human genomic DNA, per 100 µL.

If blocks have been stored in 0.5 M EDTA, wash them in 15 mL TE (see Appendix 1) for at least 2 h. Stain each block with the fluorescent dye YOYO-1 (0.33 nmol µg−1 DNA) in 100 µL of 40 mM Tris–HCl, pH 8.0, 2 mM EDTA in 2-mL Eppendorf tubes for 1 h, protecting from light. YOYO-1 staining is optional. It allows visualization of the fixed horizontal meniscus (air–solution–coverslip interface) exerts a localized, constant, downward vertical force on the immersed part of attached DNA molecules, resulting in the DNA unwinding and straightening. The hydrophobic silanized glass surface dries immediately as it is pulled out of solution. The stretched, parallel DNA molecules are irreversibly fixed on the dry glass surface. Using a cyanoacrylate glue, mount coverslips on glass slides and dry slides overnight at 60°C.

FISH has also added a new dimension to the cytogenetic analysis of structural and numerical chromosomal aberrations. It has become the most important adjunct technique to classical chromosome banding analysis, which is routinely being applied in prenatal and postnatal diagnostics and cancer cytogenetics. Because of...
its higher sensitivity, specificity, and DNA resolution, FISH can detect cytogenetically cryptic chromosome rearrangements that could not be determined previously by conventional banding methods alone. For example, microdeletions and translocations involving the chromosome some- some diseases (Figure 1a, b) appear to be an important cause of disease in patients with unexplained mental retardation(53) and most likely also in other patient populations. Similarly, patients with seemingly balanced chromosome rearrangements and a recognizable clinical phenotype may show deletions of several megabases of DNA in the breakpoint region(s). (13) Cytogenetically and genetically anchored large-insert clones for any chro- some region of interest are available for routine cytogenetics and can be adapted with unlimited flexi- bility to the study of cytogenetically cryptic and visible chromosome abnormalities.

Chromosome-specific DNA libraries are particularly useful to paint chromosomes involved in structural or numerical aberrations in both metaphase and interphase cells and to identify the chromosomal origin of marker chromosomes. Recent advances in combinatorial probe labeling and multicolor FISH allow the simultaneous visualization of all 24 human chromosomes in different colors (Figure 3). This has wide utility in cancer cytogenetics for characterizing even extensively rearranged chromosomes and karyotypes that produce very complex banding patterns. (35,36,38) In addition, CGH approaches allow one to rapidly screen tumor and patient genomes for complete and partial chromosome gains and losses and for gene amplifications (Figure 4).(18,39)

FISH has the added advantage over chromosome banding that it also detects chromosomal abnormali- ties, especially numerical aberrations, in interphase nuclei (Figure 1e, g). Chromosome-specific α-satellites produce very intense and discrete hybridization signals on inter- phase nuclei and, therefore, are frequently used to measure aneuploidy rates for individual chromosomes in tumors,(54) sperm,(55) pre-implantation embryos,(56) and other cell substrates, where metaphase chromosome preparation is difficult or even impossible. To a lesser extent, region-specific large-insert clones may also be used. Given the large contribution of chromosomes 13, 14, 21, X, and Y to constitutional chromosomal ane- uploidies, interphase assays determining copy-numbers of these chromosomes have become an important complementary tool in pre-implantation and prenatal diagnostics. (57) Specific probes spanning or binding near chromosomal breakpoints, i.e. of the Philadelphia chromosome in chronic myelocytic leukemia, allow the interphase analysis of translocations and other structural rearrangements. (58)

In addition to physical mapping and diagnostic applica- tions, FISH has proven tremendously useful for the study of genome evolution. Comparative mapping of individual gene loci has allowed the generation of homol- ogy maps in at least some important animal models. (59,60) More direct approaches to comparative genome mapping involve the delineation of contiguous conserved (syn- tetic) segments containing hundreds of homologous loci by Zoo-FISH using human (or mouse) DNA libraries on chromosomes of heterologous species. (61–63) The pres- ence of orthologous genes on interspecific homologous chromosome segments (conservation of synteny) reflects the common phylogenetic origin of species and also the ancestral genomic organization. Comparative (chro- mosome homology) maps can be used to predict the locations of homologous genes in the human and animal genomes and to answer important questions about the forces guiding mammalian genome organization, evolution, and pathology. They will also be instrumental for integrating the genetic, cytogenetic, and molecular infor- mation in human and animal species that is accumulating through genome research.

Magnesium Chloride (1 M)

\[
\text{MgCl}_2 \cdot 6\text{H}_2\text{O} \quad 203.3 \text{ g (1 M)} \\
\text{Distilled water to 1 L}
\]

MgCl\(_2\) is extremely hygroscopic. Do not store opened bottles for a long time.

\(\beta\)-Mercaptoethanol (0.1 M)

\[
\text{BME (14.4 M)} \quad 70 \mu\text{L (0.1 M)} \\
\text{Distilled water to 10 mL}
\]

Store in small aliquots in the dark at \(-20^\circ\text{C}\).

Nick Translation Buffer (10×)

\[
\begin{align*}
\text{Tris–HCl (1 M) (pH 8.0)} & \quad 5 \text{ mL (0.5 M)} \\
\text{MgCl}_2 (1 \text{ M}) & \quad 0.5 \text{ mL (50 mM)} \\
\text{BSA (10%)} & \quad 50 \mu\text{L (0.5 mg mL}^{-1}) \\
\text{Distilled water} & \quad \text{to 10 mL}
\end{align*}
\]

Postdetection Wash Solution

\[
\begin{align*}
20 \times \text{SSC} & \quad 100 \text{ mL (4 × SSC)} \\
\text{Tween 20 (10%)} & \quad 5 \text{ mL (0.1%)} \\
\text{Distilled water} & \quad \text{to 500 mL}
\end{align*}
\]

Posthybridization Wash Solution

\[
\begin{align*}
\text{Formamide (does not have to be deionized)} & \quad 50 \text{ mL (50%)} \\
20 \times \text{SSC} & \quad 10 \text{ mL (2 × SSC)} \\
\text{Distilled water} & \quad \text{to 100 mL}
\end{align*}
\]

RNase (100 mg mL\(^{-1}\))

\[
\begin{align*}
\text{RNase A (powder)} & \quad 1 \text{ g (100 mg mL}^{-1}) \\
\text{NaAcetate (C\(_2\)H\(_3\)O\(_2\)Na · 3H\(_2\)O)} (3 \text{ M}) & \quad 33 \mu\text{L (10 mM)} \\
\end{align*}
\]

Distilled water to 10 mL

Boil for 10 min to inactivate contaminating DNase activity and store in small aliquots at \(-20^\circ\text{C}\).

Saline Sodium Citrate (20 × SSC) (pH 7.0)

\[
\begin{align*}
\text{Sodium chloride (NaCl)} & \quad 175.3 \text{ g (3 M)} \\
\text{Sodium citrate (Na\(_3\)C\(_6\)H\(_5\)O\(_7\) · 2H\(_2\)O)} & \quad 88.2 \text{ g (0.3 M)} \\
\text{Distilled water} & \quad \text{to 100 mL}
\end{align*}
\]

Adjust pH to 7.0 with a few drops of 10 M NaOH and sterilize by autoclaving.

Salmon Sperm DNA

\[
\begin{align*}
\text{Salmon sperm} & \quad 1 \text{ g (10 mg mL}^{-1}) \\
\text{Distilled water} & \quad 100 \text{ ml}
\end{align*}
\]

Dissolve salmon sperm DNA in distilled water, keep in boiling water for \(\sim 30\) min so that the size range is between 100 and 500 bp, and store at \(-20^\circ\text{C}\).

Sodium Acetate (3 M) (pH 5.2)

\[
\begin{align*}
\text{NaAcetate (C\(_2\)H\(_3\)O\(_2\)Na)} & \quad 408.3 \text{ g (3 M)} \\
\text{Distilled water} & \quad \text{to 1 L (} \sim 800 \text{ mL)} \\
\text{Adjust pH with glacial acetic acid to 5.2 and adjust volume to 1 L.}
\end{align*}
\]

Sodium Dodecyl Sulfate (10%)

\[
\begin{align*}
\text{SDS} & \quad 100 \text{ g (10%)} \\
\text{Distilled water} & \quad \text{to 1 L (~900 mL)}
\end{align*}
\]

Wear a mask when weighing SDS. Heat to 68°C to facilitate dissolution of the SDS and adjust pH to 7.2 with HCl.

Taq Polymerase Buffer (10×) (without MgCl\(_2\))

\[
\begin{align*}
\text{Tris–HCl (1 M) (pH 9.0)} & \quad 1 \text{ mL (100 mM)} \\
\text{KCl (1 M) (74.55 g L}^{-1}) & \quad 5 \text{ mL (500 mM)} \\
\text{Triton X-100} & \quad 100 \mu\text{L (1%)} \\
\text{Distilled water} & \quad \text{to 10 mL}
\end{align*}
\]

Buffer is usually supplied with the enzyme.

TE

\[
\begin{align*}
\text{Tris–HCl (1 M) (pH 7.4)} & \quad 1 \text{ mL (10 mM)} \\
\text{EDTA (0.5 M)} & \quad 0.2 \text{ mL (1 mM)} \\
\text{Distilled water} & \quad \text{to 100 mL}
\end{align*}
\]

Tris–HCl Buffer (1 M) (pH 7.4)

\[
\begin{align*}
\text{Tris base} & \quad 121.1 \text{ g} \\
\text{Hydrochloric acid (HCl conc.)} & \quad \sim 70 \text{ mL}
\end{align*}
\]
**FLUORESCENCE IN SITU HYBRIDIZATION**

Distilled water to 1 L
Cool; adjust to pH 7.4 and add distilled water to 1 L; autoclave.

**Tris–HCl (1 M) (pH 8.0)**

- Tris base 121.1 g
- Hydrochloric acid (HCl conc.) 42 mL
- Distilled water to 1 L

**Tween 20 (10%)**

Stir for at least 10 min to completely dissolve the Tween 20 and store at 4°C.

**REFERENCES**

A physical map of a region or the entirety of the genome of an organism is a representation of the genome providing information on the relative order and the arrangement of physically defined entities. For most physical maps, these entities are cloned genomic DNA fragments propagated in cosmids, bacteriophage P1, bacterial artificial chromosomes (BACs), P1-derived artificial chromosomes (PACs), or yeast artificial chromosomes (YACs). The various cloning systems differ in the sizes of the cloned DNA fragments and the fidelity of DNA structure maintenance. Owing to its excellent properties, the BAC system is the premier system currently available for cloning and maintenance of large genomic DNA.

In contrast to a physical map, the genetic map of the genome of an organism is a rather imaginary map, which is based on the frequencies of recombination (crossing over) events occurring between genetic loci. These loci are defined either as mutations in genes that are identified through alterations in the properties of the organism (phenotypic changes) or as polymorphic DNA fragments, the sequence differences of which can be monitored directly or indirectly.

The establishment of a physical map of a genome is an intrinsic part of a detailed genome analysis. In particular, when linked to the genetic map, a high-resolution physical map is of high value for studies
devoted to genome organization and function, including the elucidation of the relations of physical to genetic distances and for the coordination and performance of sequencing projects. Its immediate value to the research community, however, may be even higher through the strong support it provides to map-based gene-cloning efforts. Through this procedure, genes could be isolated and studied at the molecular level that are only characterized by a corresponding mutant phenotype (alteration in morphological, developmental, metabolic, or behavioral properties of an organism caused by the genetic change). The availability of this procedure thus provides a means to gain entirely novel information on the molecular mechanisms underlying the multitude of processes occurring in living organisms.

2 DNA CLONING SYSTEMS APPLICABLE TO PHYSICAL MAPPING EXPERIMENTS

To be useful for the application of physical mapping procedures, a DNA cloning system has to meet several requirements. Higher eukaryotic organisms usually have genomes of enormous sizes, which may range from ca. 97 Mbp as in the case of the nematode *Caenorhabditis elegans,*\(^{(1)}\) 130 Mbp in the case of the plant *Arabidopsis thaliana,*\(^{(2)}\) ca. 165 Mbp in the case of the fruit fly *Drosophila melanogaster,*\(^{(3)}\) ca. 430 Mbp for rice (*Oryza sativa*)\(^{(4)}\), ca. 3 Gbp in the case of man (*Homo sapiens*)\(^{(5)}\) and corn (*Zea mays*\(^{(6)}\), and up to 16 Gbp for wheat (*Triticum aestivum*\(^{(7)}\)). Of major importance, therefore, is the size of DNA fragments, which can be cloned and stably maintained in a particular cloning system. The size of the DNA fragments determines the number of clones to be handled in order to represent (nearly) the entire genome. To provide sufficient coverage of the genome, a genomic library of a minimum of 10-fold genome representation (number of clones in the library × average insert size/genome size) should be used for a physical mapping project.\(^{(7)}\) This extensive coverage is required to ensure a very high probability of representation of every region in the genome and to provide sufficient overlap between the individual clones to be detectable by the mapping procedure. Thus, in the case of a 100-Mbp genome, a library of ca. 100,000 clones would be necessary in the case of an average insert size of 10 kbp, a library of ca. 10,000 clones would be necessary in the case of an average insert size of 100 kbp, and a library of ca. 1000 clones would be sufficient in the case of an average insert size of 1000 kbp (= 1 Mbp). The number of clones would influence not only the effort required for ordered handling, but also the number of experiments to be performed for ordering them (see below). Although clone libraries with very large insert sizes are advantageous in terms of reducing the amount of labor for handling and processing, they are disadvantageous, on the other hand, in terms of the resolution achieved. Since robotic devices have been developed, which allow the handling of very large numbers of clones (in the range of 100,000),\(^{(8)}\) the balance between the number of clones to be handled/number of experiments to be done and the resolution achieved may be shifted more and more toward the latter. A second important criterion is the quality of the DNA represented in the clones of the library. Various DNA cloning systems differ strongly in the fraction of aberrant clones, which may be chimeric (composed of DNA fragments derived from different, noncollinear regions of the genome that were fused upon cloning), may carry rearranged DNA fragments, or may have suffered from deletions. The latter two changes in the cloned DNA fragments may occur not only during the cloning procedure itself, but also during clone propagation. Finally, various cloning systems differ in their properties in terms of handling, including the requirements for culture and/or storage of the clones, or the procedures used for the isolation of the cloned DNA.

Several different DNA cloning systems are available; the major properties and advantages/disadvantages will be mentioned briefly in the following sections before the preferred BAC system is described in more detail.

2.1 Cosmids

Cosmids are vector systems for propagation of DNA fragments in the bacterial host *Escherichia coli.*\(^{(9)}\) Owing to the specific cloning procedure, which involves packaging of the DNA molecules into bacteriophage \(\lambda\) particles, the size of inserted DNA fragments is limited to a maximum of ca. 50 kbp. Various different cosmid vectors are available, which may differ in the stability of the cloned DNA fragments. Routine procedures are available for the generation, handling and storage of cosmids.\(^{(9)}\)

2.2 Bacteriophage P1

The bacteriophage P1-based DNA cloning system also relies on the bacterial host *E. coli* for propagation.\(^{(10)}\) In analogy to the cosmid system, DNA molecules are packaged into phage P1 particles for delivery into the *E. coli* cells. Advantageous in comparison to the cosmids is the increased size of the packaged DNA molecules, which allows a maximum insert size of ca. 100 kbp. Although a variety of P1 libraries have been established in various laboratories, the P1 cloning procedure cannot be regarded generally as a routine.
2.3 Yeast Artificial Chromosomes

YACs are propagated in the bakers’ yeast Saccharomyces cerevisiae as linear molecules (chromosomes) equipped with centromeric and telomeric sequences, elements required for initiation of replication, and selectable marker genes. A variety of YAC libraries have been established for animals, plants, and humans, which proved the suitability of the YAC system to clone very large DNA fragments (above 1 Mbp) and which displayed average insert sizes ranging from ca. 100 kbp up to 800 kbp. Although YACs are superior to all other DNA cloning systems in terms of the size of the inserted DNA fragments, this cloning system suffers from two major disadvantages. In many YAC libraries, very large fractions of clones (up to 40 or 50%) carry aberrant, nonauthentic DNA fragments (showing chimerism, rearrangements, deletions, and/or instability). A very high proportion of the results obtained on YAC clones during the course of a physical mapping project may thus be erroneous and may require the investment of additional very strong efforts for their identification and elimination. The fraction of aberrant clones may, however, be reduced through the use of optimized yeast strains. Other limitations of this system are the procedures for handling and processing of the clones, which in general are more laborious than for the E. coli-based systems. This is particularly true for the procedures to be applied for the isolation and purification of the cloned DNA fragments.

2.4 Bacterial Artificial Chromosomes and P1-derived Artificial Chromosomes

2.4.1 Characteristics of the Systems

These two DNA cloning systems rely on the host system E. coli, which thus provides the opportunity to apply (almost) all routine procedures for clone propagation, handling, and storage that are usually established in molecular biologically oriented laboratories. The BAC system has been developed on the basis of an F-plasmid-derived replicon, which includes the factors that control the number of plasmid copies per bacterial cell to be 1–2. This system has been demonstrated to be capable of taking up and stably maintaining large DNA fragments (up to a size of ca. 350 kbp). Apparently, the strict copy number control exerted by this system is the key to the highly faithful representation of the genomic DNA molecules and their very stable propagation. The developed BAC vectors, such as pBAC108L, pBeloboBAC11, pECBAC1, or pBeloBAC-Kan (see Figure 1), display a variety of favorable features. These include multiple cloning sites flanked by recognition sites for rare cutting restriction enzymes (useful for the excision of the cloned DNA fragments), a lacZ-based reporter system to monitor recombinant clones, and the presence of bacteriophage T7 and SP6 promoters flanking the cloning site (useful for the generation of labeled end-probes; see below). Specific BAC vector variants such as pBiBAC or pTAC have been created, which allow their use in Agrobacterium tumefaciens-mediated transfer of the inserted DNA into plants. This opens the attractive opportunity to transfer cloned large DNA fragments into plants, providing the means to identify rapidly novel genes or to identify and transfer quantitative trait loci. The PAC resembles the BAC vector, but

![Figure 1](https://example.com/figure1.png)

Figure 1 Schematic representation of the pBeloBAC-Kan vector. Indicated are the functional elements involved in replication and copy number control (oriS, repE, parA, parB), the selectable marker (Kanamycin resistance), and details of the multiple cloning site. The latter is flanked by the phage T7 and SP6 promoters suitable for the generation of labeled end-probes and is located within the lacZ gene that allows blue/white selection for recombinant clones. The cloning site is furthermore flanked by recognition sites for rare cutting restriction enzymes, and loxP and cosN sites are present, which may be used for the high-specificity cleavage.
is based on the P1 replicon and carries a marker for the selection for recombinant clones (sacB). In contrast to the aforementioned P1 cloning system (section 2.2), PACs, like BACs, are introduced into the \textit{E. coli} host cells by electroporation. The sizes of the recombinant BAC or PAC molecules are therefore not limited by the capacity of phage particles for DNA uptake.

Several BAC and PAC libraries have been established recently for plants,\textsuperscript{41,45–49} animals,\textsuperscript{50–53} and humans,\textsuperscript{39,44,51} with average insert sizes ranging from ca. 100 kbp up to 235 kbp. These libraries provide deep genomic coverages and easy access to high-quality genomic DNA suitable for manipulation, such as sequencing, exon trapping, complementary DNA selection, microsatellite marker isolation, and fluorescence in situ hybridization studies.\textsuperscript{38,54–57}

### 2.4.2 Generation of a BAC Library

For the generation of a BAC library, several experimental steps are necessary (see Figure 2; for a detailed description of the BAC cloning procedure, see Shizuya et al.\textsuperscript{38} and Mozo et al.\textsuperscript{41}):}

![Arabidopsis BAC Cloning Diagram](image-url)

**Figure 2** BAC cloning procedure applied for the generation of an \textit{Arabidopsis thaliana} BAC library. In this case, protoplasts prepared from root-derived suspension cultures were used as a source of high-molecular-weight DNA prepared through proteinase K digestion after embedding in agarose. The high-molecular-weight DNA was partially digested by EcoRI restriction enzyme/methylase competition, fractionated by preparative pulsed-field gel electrophoresis (PFGE), concentrated and ligated into the pBeloBAC-Kan vector. Ligation products were transfected into \textit{E. coli} by electroporation and white colonies grown in the presence of X-Gal/IPTG (substrate and inducer of the lacZ gene) were picked and stored at $-70^\circ$C in microtiter dishes.
1. High-quality high-molecular-weight DNA (≥1 Mbp) has to be prepared from the source organism. This may be achieved by agarose embedding of cells or protoplasts (plant cells without cell wall) or nuclei and liberation of the DNA by a proteinase digestion.

2. This DNA has to be partially digested with a suitable restriction enzyme (such as BamHI, Sau3A, HindIII, EcoRI) to yield DNA fragments in the desired size range (150–250 kbp). The limited digestion can be achieved by limited incubation time, suboptimal (e.g. low temperature) incubation conditions, or by a competition reaction of restriction enzyme and a corresponding methylase. The last possibility has the advantage over the first two of allowing the reaction to be run to completion, which is of relevance if the available high-molecular-weight DNA concentration is low.

3. The DNA fragments of the desired size range have to be separated from the molecules of smaller size that inevitably also occur and would be preferentially cloned subsequently. PFGE is used to separate the large DNA molecules. Usually, at least two successive rounds of PFGE under different conditions are necessary to achieve sufficient purification. In the case of low DNA concentrations, a subsequent step for DNA concentration may be necessary/desirable through another electrophoresis involving an agarose gel of higher concentration.

4. The insert DNA fragments thus generated are released from the agarose matrix by enzymatic digestion of the agarose and the liberated DNA molecules are ligated to dephosphorylated pBAC vector DNA.

5. The ligation products are transferred into E. coli cells by electroporation under optimized conditions that are favorable for the uptake of large molecules. Depending on the BAC or PAC vector used, recombinant clones may be recognized through the expression of scorable (e.g. lacZ) or selectable marker systems (e.g. sacB). Recombinant clones are picked into liquid culture medium (preferably in microtiter plates) and transferred to −70°C for long-term storage. For propagation (e.g. library replication), establishment of colony filters for DNA hybridization experiments (see below), or BAC DNA preparations, standard E. coli handling procedures can be applied. To verify the presence of high-quality recombinant clones, a set of randomly selected clones should be tested for insert sizes by BAC DNA isolation, digestion with an appropriate rare cutting restriction enzyme (e.g. NotI) and PFGE.

3 APPROACHES TO PHYSICAL MAPPING

Various techniques are available for identification of overlapping clones, which essentially is the information to be gathered during a physical mapping program. To this end, experiments are designed to group efficiently as many clones as possible into contigs (contiguous sequences). Several procedures have been developed that rely on different types of information to detect the presence of common DNA regions in different clones.

3.1 Hybridization-based Procedures

The property of DNA molecules to be composed of two complementary strands is used in hybridization experiments. Thus, DNA molecules can be identified through hybridization to carry identical or highly similar sequences. Screening of a clone library by hybridization is usually done after fixation of DNA liberated from the clones to a solid support, e.g. a nylon membrane (see Figure 3). The immobilized DNA is then incubated with a labeled probe (a certain species of radioactively, fluorescently, or digoxigenin-labeled DNA molecules) under appropriate conditions. Through the detection of the label at specific positions of the filter, the identity of the corresponding (overlapping) clone can be determined. It is particularly advantageous when applying such a procedure to use gridded libraries, the clones of which are fixed to defined positions on the filter.

In this case, large numbers of hybridizations can be performed efficiently and the results of the hybridizations can be evaluated rapidly. This approach has gained strong support by the development of robotic devices, which provide the means to fix at high precision very large numbers of clones at high density to membranes that can be produced in large quantities. The labeled probes used may be derived from individual selected clones (chromosome walking), they may be oligonucleotides (hybridization fingerprinting), or they may be genetically mapped markers (anchoring). Relatively short stretches of sequence identity are sufficient to detect overlaps by hybridization, which is thus useful also for genomic regions of sparse coverage in the libraries used.

The information gathered by hybridization, however, does not provide any indication of the degree of overlap between clones. Such information may be obtained, for example, by application of the DNA fingerprinting technique (see section 3.3). Erroneous hybridization results may be generated through the appearance of highly related DNA sequences present at different regions in the genome. The specific properties of the genome investigated therefore strongly influence the viability of a hybridization-based mapping approach. Because all

Figure 3 Physical mapping through hybridization. To identify overlap between clones of an ordered large insert library, labeled DNA probes (e.g. derived from clones of the library) are hybridized to the DNAs of the clones fixed to a solid support (e.g. a nylon membrane). The procedure is most efficiently performed in an iterative manner ("sampling without replacement") by preparing new labeled probes only from clones that have not been hit by any previous hybridization. Established contigs eventually merge through clones hit by more than one probe. Here, D14 is a connecting clone; it is marked in green on the filter because it was identified by the probe derived from clone D22 (marked in blue) and by the probe derived from clone C22 (marked in yellow).
clones of the library are checked for overlap with the probe at the very same time, hybridization is intrinsically highly parallel and it has an extremely high throughput. In addition, it readily allows the integration of data generated by the application of different types of probes, such as clones from different libraries (e.g. cosmid, BAC, or YAC clones), total labeled clones or clone end-probes, or mapped markers. The use of the latter type of probe is highly desirable because it would result in an alignment of the physical map with the genetic map.

An efficient procedure for the generation of contigs (physical mapping) through iterative hybridization has been developed and applied successfully to generate high-resolution cosmid and P1 maps of Schizosaccharomyces pombe. The strategy of “sampling without replacement” (see Figure 3) was applied here, which involves the selection of clones to be labeled and hybridized to the complete genomic libraries from only the subset of clones never hit by any of the previous hybridizations. This procedure greatly reduces the number of hybridization reactions that have to be carried out in comparison to random probe selection. A modification of this procedure involves the generation of hybridization probes from both ends of the selected clones. In addition to generating larger contigs than through the use of single end-probes, the double end-probe procedure provides information on the relative orientation of the identified clones. The latter approach recently was applied successfully to the generation of the first BAC-based physical map (see section 4).

The efficiency of the “sampling without replacement” procedure is limited by the frequency of repetitive sequences present in the cloned DNA fragments, which may comprise very substantial fractions of large eukaryotic genomes. The presence of such repetitive sequences within the labeled probes would cause the generation of noninformative results. In this situation it is advisable to use oligonucleotides as probes or to select DNA probes from sources enriched for single/low-copy sequences such as complementary DNAs, identified as expressed sequence tags (ESTs).

3.2 Methods Based on Polymerase Chain Reaction

Sequence-specific DNA amplification via PCR provides another efficient means to test recombinant clones for the presence of a particular piece of DNA. Thus, specific pairs of oligonucleotide primers designed according to the sequences of known stretches of DNA are applied in large sets of amplification reactions containing DNAs isolated from the various different clones of a genomic library as templates. Because DNA amplification to detectable levels would only occur in those reactions supplied with template DNA derived from clones carrying the cognate DNA region, PCR can be used as a very sensitive and reliable assay for the presence/absence of specific DNA sequences, even in complex mixtures. The DNA regions of known sequence have been termed “sequence-tagged sites” (STSs) and the corresponding mapping procedure is known as “STS content mapping” (see Figure 4).

The major advantage of STS content mapping over the use of cloned DNA fragments, e.g. as hybridization probes, is the immediate access to any STS by any interested laboratory as soon as it is made known. An STS can be defined completely as information (essentially a short stretch of DNA sequence plus instruction for the PCR assay) that can easily be deposited in a database. No access to specific biological material such as a cloned DNA fragment, which initially might have led to the identification of an STS, is required to perform an STS assay. This “common language” provides an ideal basis for collaborative approaches between many geographically dispersed groups, as may frequently be the case for mapping projects devoted to the analysis of very large and complex genomes. A further advantage of STS content mapping is its applicability even to genomic regions rich in repetitive sequences, provided that these sequences are interspersed with single-copy sequences that can be used for primer design.

Disadvantages of STS content mapping include the requirement for quite large amounts of sequence information to be available prior to the initiation of a mapping project or to be produced during the conductance of the project. The PCR method itself bears the risk of producing false negative (lack of DNA amplification in cases where it should occur) and false positive results (DNA amplification in cases where it should not occur). These need to be identified through proper controls and may require additional efforts for the optimization of PCR conditions. Owing to the need for performance and evaluation of very many DNA amplification reactions (see below), this procedure is very labor- and cost-intensive.

STS content mapping usually involves the isolation of DNA from a specific subset or, for all clones, from an ordered large insert library, and subjecting these DNAs to individual STS assays that include PCR amplification and evaluation of the PCR products. Because the clone libraries usually consist of several tens of thousands of clones and several thousand STSs have to be tested for the construction of genome-wide maps, several million STS assays may have to be performed. It is therefore almost inevitable that appropriate clone pooling strategies are used, which provide an efficient means to reduce the number of STS assays required but still allow the identification of individual positive clones (see Figure 4). To be able to process the enormous numbers of STS assays (≥15 million
**Figure 4** Physical mapping through application of PCR. After multidimensional pooling of clones of an ordered large insert clone library, DNA prepared from the clone pools is subjected to PCR using single-copy-sequence (STS)-specific oligonucleotide primers. Successful amplification highlights the presence of a clone within the positive pool that carries the particular DNA sequence. The information obtained on the various pools is deconvoluted to identify individual positive clones. In the case of STS 1 (marked red), a positive signal was detected in column pool 22 and row pool E of plate 1. The positive clone therefore is clone E 22 from plate 1 (1 E 22). Clone contigs are established according to the presence of common STSs; contigs eventually merge through clones hit by more than one STS.

Perform image analysis to identify common DNA fragments and to determine their sizes

Use information about common DNA fragments for contig assembly

Figure 5 Physical mapping through DNA fingerprinting. DNA isolated individually from all clones of an ordered large insert clone library is treated with a restriction endonuclease and the resulting DNA fragments are separated according to their size by gel electrophoresis. Overlap between clones is detected through the presence of common bands in the gel image, which correspond to common DNA fragments. Contigs are established according to the information about common DNA fragments (marked in red, green, and blue) carried by the clones.
have been performed during the construction of a human STS-based map,\textsuperscript{73} and $\geq 17$ million for establishing a map of the mouse genome\textsuperscript{74}, large-scale automation systems are required. Analogous to the hybridization-based approaches, specific optimized procedures for selection of the STSs\textsuperscript{68} may be applied to limit the number of necessary STS assays. Nonrandom selection of STSs was applied successfully for the generation of a physical map of the Drosophila euchromatic genome.\textsuperscript{75} In addition to the aforementioned physical maps of entire genomes, a large number of YAC-, P1-, PAC-, or BAC-based maps for specific chromosomes or chromosomal regions have been established through involvement of STS content mapping.\textsuperscript{76–83}

3.3 DNA Fingerprint Analysis

The property of DNA restriction enzymes to cleave DNA molecules at specific recognition sequences provides the basis for another type of procedure for the recognition of the presence of common (identical) DNA stretches: when digested with an appropriate restriction enzyme, DNA molecules are cleaved into a specific pattern of DNA fragments that form a characteristic pattern of bands when separated by gel electrophoresis and visualized (DNA fingerprinting\textsuperscript{84}). In the case of two clones sharing a common stretch of DNA, this would give rise to a number of common DNA fragments that can thus be used to detect overlaps (see Figure 5). The probability of detection of true overlaps by this procedure is determined by the number of common fragments and the size of the analyzed genome. This procedure has been applied successfully for mapping all or parts of the genomes of Caenorhabditis elegans,\textsuperscript{84,85} yeast,\textsuperscript{86,87} E. coli,\textsuperscript{88} Drosophila melanogaster,\textsuperscript{89} and humans.\textsuperscript{30,90–92}

In comparison to hybridization, much more extended regions of sequence identity are required to provide a sufficient number of common DNA fragments for the exclusion of similarly sized DNA fragments appearing by chance. Therefore, a high redundancy of the clone libraries is an essential prerequisite and very many clones have to be fingerprinted to generate a complete physical map.\textsuperscript{30} Furthermore, analytical systems that permit precise and reproducible DNA fragment sizing and data acquisition in a high-throughput fashion are necessary. Automated methods are therefore required to pursue this approach, which has been further developed to be applicable to very-high-throughput analysis.\textsuperscript{93} In contrast to hybridization, however, DNA fingerprinting is less prone to producing erroneous results caused by the appearance of highly related DNA sequences present at different regions in the genome. Furthermore, the results of a DNA fingerprint analysis provide information on the extent of overlap of clones derived from the number and the sizes of common DNA fragments. This information is of particular relevance for the selection of a minimal set of clones spanning a certain region, e.g. for sequencing.

3.4 Clone (End-) Sequencing (Sequence-tagged Connector Approach)

As a fourth type of approach and a complement to the DNA fingerprinting approach, Venter et al.\textsuperscript{94} proposed a procedure for mapping clones primarily based on sequence analysis, which has come within reach through the enormous increases in DNA sequencing capacity. The principle underlying this approach is the identification of overlap between clones directly through the identification of a common DNA sequence (see Figure 6). To this end, a large collection of BAC clones, such as a BAC library representing an average 15-fold genome representation, is analyzed by sequencing both ends of the inserted DNA fragments and a corresponding end-sequence database is established. Starting with a “seed-BAC” that is completely sequenced, all overlapping BACs are recognized through a stretch of common DNA identified upon search of the end-sequence database. This approach is cost effective, especially for very large genome sequence analysis projects, and has proven to be highly viable, e.g. for the Arabidopsis thaliana sequencing project (S. Rounsley, personal communication). Because it relies rather exclusively on sequence analysis and the physical map is actually developed through the complete genomic sequencing, it is only applicable to mapping genomes that are intended to be fully sequenced.

4 BAC-BASED PHYSICAL MAPPING OF THE ARABIDOPSIS THALIANA GENOME

Arabidopsis is a small flowering plant that today serves as the major model system in plant molecular genetics\textsuperscript{95} and that has been chosen as the subject of the first large-scale project intended to determine the full genome sequence of a plant.\textsuperscript{96} This sequencing project, together with the increasing interest in map-based gene cloning, has highlighted the requirement for a complete and accurate physical map of this plant species. Two complementary approaches have been initiated to achieve this goal.\textsuperscript{96,97} The final merging of the data produced by these two approaches recently led to the establishment of the first reported map of a complex organism based entirely on BAC clones. This map represents the most homogeneous and complete physical map established to date for any plant genome.\textsuperscript{70}

In the first of the two approaches, the aforementioned “sampling without replacement” procedure of high-throughput hybridizations of BAC end-probes was
Figure 6 Physical mapping through DNA sequencing. The DNA sequences located at the ends of the cloned DNA fragments of every clone of an ordered large insert clone library are determined and deposited in a database. Thereafter, an individual clone ("seed clone") is selected for complete sequencing. This sequence information is used to search the end sequence database for sequence identities. Matches between the sequence of the "seed clone" and end sequences of other clones demonstrate the presence of common DNA regions within the cloned DNA fragment of the various clones and provide the means to determine precisely the degrees of overlap. Clones with minimal overlap to the "seed clone" are selected for sequencing of the entire inserted DNA fragment and the elucidated sequence is used again to query the end sequence database. Through this procedure, a clone-based physical map of a genome is established simultaneously with the determination of the entire genome sequence.

applied because it was shown to work efficiently for this organism. The nuclear DNA of Arabidopsis thaliana, which is estimated to cover ca. 130 Mbp, is characterized by a low content of interspersed repetitive sequences. It is therefore particularly well suited for the application of a hybridization-based physical mapping approach. When evaluated on the basis of 1000 end-probe hybridization experiments, the applied "double-end-probe sampling without replacement" approach was found to be highly efficient, with about 50% of all mappable clones identified and assembled into a minimum of 220 contigs. However, the results obtained deviated slightly from theoretical predictions in that a lower than expected fraction of the genome was covered by the assembled...
contigs. This result might have been caused by a non-random genome representation in the BAC library used. An intriguing 200-kb periodicity of over- and under-represented regions has been observed in an independent study. A total of more than 3000 hybridization experiments was performed on a 10752 clone BAC library, representing ca. 7 genome equivalents. The results of 2723 hybridization experiments were included in the final map, which were complemented by 272 genetic marker data.

In the second approach, a high-throughput BAC DNA fingerprint analysis was performed on a set of 21403 Arabidopsis thaliana BAC clones, of which 20206 successfully yielded fingerprint data. Using the FPC software for automated assembly of contigs based on the fingerprint data and by manual editing, a total of 169 contigs containing at least 3 BAC clones and another 124 contigs containing 2 BAC clones were assembled. These 293 contigs contained 19909 BAC clones.

To assemble the final map, the results obtained by the hybridization experiments were merged with the BAC fingerprint data by querying the latter for the presence of BAC clones not identified in the hybridization experiments and for clones closing gaps between the previously established contigs. Ninety-nine connections shown in the map were inferred exclusively from this information. In addition, the fingerprint data were particularly useful to solve conflicting hybridization data (due to cross-hybridization) and to assemble and extend contigs of clones containing repetitive sequences. The map (displayed at http://www.mpimp-golm.mpg.de/101/mpi_map/access.html) consists of 27 contigs that cover the entire Arabidopsis thaliana nuclear genome, except for the presumptive centromeric regions, nucleolar organization regions, and telomeric areas. The 27 contigs are distributed over the 10 chromosome arms leaving 14 gaps, 12 of which are bridged by YAC, P1 or PAC clones. The genome, except for the presumptive centromeric regions, nucleolar organization regions, and telomeric areas. The 27 contigs are distributed over the 10 chromosome arms leaving 14 gaps, 12 of which are bridged by YAC, P1 or PAC clones. These 293 contigs contained 19909 BAC clones.

To assemble the final map, the results obtained by the hybridization experiments were merged with the BAC fingerprint data by querying the latter for the presence of BAC clones not identified in the hybridization experiments and for clones closing gaps between the previously established contigs. Ninety-nine connections shown in the map were inferred exclusively from this information. In addition, the fingerprint data were particularly useful to solve conflicting hybridization data (due to cross-hybridization) and to assemble and extend contigs of clones containing repetitive sequences. The map (displayed at http://www.mpimp-golm.mpg.de/101/mpi_map/access.html) consists of 27 contigs that cover the entire Arabidopsis thaliana nuclear genome, except for the presumptive centromeric regions, nucleolar organization regions, and telomeric areas. The 27 contigs are distributed over the 10 chromosome arms leaving 14 gaps, 12 of which are bridged by YAC, P1 or PAC clones. These 293 contigs contained 19909 BAC clones.

This report demonstrates the strong advantage of having available two large sets of data generated by the use of different techniques and approaches (which proved to be complementary rather than redundant) to achieve the goal of rapidly and efficiently establishing a complete physical map of a complex genome.

Nucleic acids are prone to fragmentation in the ionization process of mass spectrometry (MS). The cause can be found in the polar nature of this analyte class. Following the introduction of the so-called soft-ionization techniques of electrospray ionization (ESI) and matrix-assisted laser desorption ionization (MALDI) at the end of the 1980s, mass spectrometric analysis of nucleic acids has gained broader applicability. In combination with further developments of the associated instrumentation and optimized preparation and purification methods, a dramatic enhancement of the mass range, detection sensitivity, and resolution became possible – in routine analysis oligonucleotides up to a length of 50 nucleotides are accessible. At present the necessary quantity of sample is in the subfemtomole range.

This article describes the fundamentals of mass spectrometric analyses of nucleic acids and common applications, such as the analysis of noncovalent complexes, mixture analysis, different sequencing strategies and clinical diagnostics. The focus is on MALDI/MS (matrix-assisted laser desorption ionization/mass spectrometry).

---

1 **INTRODUCTION**

Characterization of nucleic acids by MS has always been both a challenging and promising endeavor. Since 1962, when the first mass spectra of nucleosides obtained with electron impact mass spectrometry (EI/MS) were reported, MS has gained importance in nucleic acid analysis.

Although the classical ionization techniques (electron impact (EI) and chemical ionization (CI)) were limited in analyte size to dinucleotides, they were successfully employed for the structural analysis of nucleic acid constituents (i.e., nucleobases, nucleosides, nucleotides) and had their significance especially in the elucidation of posttranscriptional processings of RNA and DNA. The limitation to dinucleotides is a result of the polar nature of the analyte and the elevated tendency to fragmentation (thermal decomposition predominates volatilization).

Chemical derivatization of the analyte was often necessary to enhance the volatility and to reduce fragmentation for MS examination. Hunt et al. intensively studied per(trimethylsilyl) derivatized dinucleoside monophosphates with EI/MS. In addition to the molecular ions they observed sequence-specific fragment ions. As dinucleotides are the smallest nucleic acid subunit that contains sequence information, these studies paved the way for direct MS sequencing. The investigation of all four underivatized di-2′-deoxyribonucleoside monophosphates showed no molecular ions, but fragment ions in terminus-related intensities. However, diribonucleoside monophosphates were found to be much more stable, a feature attributed to the 2′-hydroxyl group. Unprotected dinucleotide monophosphates could be analyzed with field desorption (FD) MS, but it was found that this technique was experimentally difficult to handle with low run-to-run reproducibility.

The analysis of oligonucleotides became feasible with the introduction of plasma desorption (PD), secondary ion (SI), and fast atom bombardment (FAB) MS.

Positive ion spectra of plasma-desorbed protected oligonucleotides showed mostly cationized quasimolecular ions with a size limit of nine nucleotides. In the negative ion mode distinctive fragment ions could be observed in addition to the deprotonated quasimolecular ions. The fragmentation pattern showed two complementary series retaining either of the two termini of the nucleotide strand. Beginning with the more intense series of fragment ions containing the 5′ terminus, these fragments bear the phosphate group at their 3′ end after cleavage of the respective 5′ C—O bond and, correspondingly, the 3′ terminus series carries the phosphate group at the 5′ end after cleavage of the 3′ C—O bond. SIMS (secondary ion mass spectrometry) revealed the
attachment of Na\(^+\) and Cs\(^+\) to the molecule in the positive ion mode and intact quasimolecular ions in the negative ion mode.\(^{16}\) Wu et al.\(^{17}\) reported an enhanced ionization efficiency with SIMS if the analyte was mixed with a typical MALDI matrix (e.g. dihydroxybenzoic acid). This technique made it possible to detect a DNA 26-mer with only minor fragmentation. The pioneering work on MS oligonucleotide sequencing was performed by Grotjahn et al. who compared the mass spectra of more than 100 oligomers obtained by negative ion mode FAB/MS (fast atom bombardment/mass spectrometry).

These workers deduced rules for deriving sequence information from fragment ion patterns.\(^{18,19}\) Two major fragment ion series were detected: one more intense with the so-called 5' sequence ions bearing a 5' phosphate group, and a second one with the phosphate group at the 3' end (3' sequence ions). It is noteworthy that this description may be misleading: the 5' sequence ions (3' sequence ions) only carry the phosphate group of the cleaved phosphodiester bond at their 5' end (3' end), but contain the 3' terminus (5' terminus) of the oligonucleotide. Although additional fragmentation (−18 Da, explained as loss of water and +80 Da, described as +HPO\(_3\) artifacts) was observed, bidirectional sequencing based on these two distinct fragment ion series was proposed. This concept for sequencing unknown oligonucleotides relied on the assignment of the more intense series to the so-called 5' sequence ions. It was reported that this was indeed the more intense series for 8-mers but not for 2–4-mers. Other researchers also questioned the predominance of the 5' series.\(^{20,21}\) The complete bidirectional sequence information could be obtained for up to a 10-mer using about 10 nmol of sample.\(^{19,22}\) Although efforts were made to increase the accessible mass range of oligonucleotides for FAB/MS the biggest detected intact oligonucleotide was an RNA 24-mer.\(^{23}\) A detailed comparison of these ionization methods for short oligonucleotides with special consideration of the fragmentation is given by Crain.\(^{22}\)

The introduction of ESI by Fenn et al.\(^{24}\) and MALDI by Karas and Hillenkamp\(^{25}\) in the late 1980s opened a new chapter in MS nucleic acid research. Further development of the associated instrumentation in combination with optimized preparation and purification methods led to dramatic increases in the accessible mass range, resolution, and sensitivity.\(^{26–30}\)

### 1.1 Characteristics of Nucleic Acids Under Mass Spectrometric Conditions

ESI and MALDI exhibit similarities but also differences due to the respective ionization technique. In ESI, an analyte solution is sprayed through a needle into an electrical field and ionized via repetitive coulombic bursting of the generated droplets until the fully desolvated analyte ions finally enter the mass analyzer. For a MALDI analysis, the analyte solution is mixed with a matrix (organic substance in a high molar excess) and deposited on a metallic sample support. For solid matrices used predominantly in MALDI with ultraviolet (UV) laser wavelengths (UV/MALDI), the volatile solvent is evaporated leaving a polycrystalline sample behind. Vacuum-stable liquid matrices such as glycerol are used predominantly in MALDI with infrared (IR) wavelengths (IR/MALDI) and the matrix/analyte preparation is transferred directly into the spectrometer. Both analyte and matrix molecules are desorbed and ionized in an interaction of the sample with a high intensity laser light pulse of nanosecond duration.

In solution, the polyamionic backbone of nucleic acids is fully dissociated as a result of the pK\(_a\) values of the backbone phosphates being less than 1 (for a comparison, phosphoric acid has a pK\(_a\) of 2.1).\(^{31}\) The pK\(_a\) values of all protonated nucleobases but the uracil (U) derivatives (pK\(_a\) ≈ 10) vary from 3.5 to 5.\(^{31}\) For ribonucleosides the pK\(_a\) values are 4.2 for cytidine, 3.5 for adenosine, and 2.4 for guanosine. These values are only slightly less than those for the deoxyribonucleosides. Due to the electrostatic interaction of the negatively charged phosphodiester groups with the protonated bases, the respective values are decreased in nucleotides by 0.2–0.5 pK units.\(^{31}\) These variations may occur because of the more complex interactions possible within bigger molecules. It should be kept in mind that ionic strength\(^{32}\) and temperature\(^{33,34}\) both influence the ionization constants. Kochetov and Budovskij\(^{35}\) evaluated the possible protonation sites of the nucleobases and stated that they are N1, N3 and N7 for adenine (A), N3 and N7 for guanine (G) and N3 for cytosine (C). The same authors reported that X-ray spectroscopic, and NMR studies revealed N1 in A and N7 in G as favored protonation sites (Figure 1).\(^{35}\)

As the molecules are transferred into the gas phase for mass spectrometric analysis, the gas-phase acidities and basicities must be considered for the interpretation of the mass spectra, especially to account for process-induced fragmentation. Greco et al. determined the following order of proton affinities for deoxyribonucleoside 5' monophosphates (dNMPs): dGMP (234.4 kcal mol\(^{-1}\)) > dAMP (233.6 kcal mol\(^{-1}\)) ≈ dCMP (233.2 kcal mol\(^{-1}\)) > dTMP (224.9 kcal mol\(^{-1}\)).\(^{36}\) Similar values can be expected for the related ribonucleosides. The proton affinity of the phosphodiester group has not been determined experimentally, but was deduced from the known value for triethylphosphat as 220–225 kcal mol\(^{-1}\).\(^{37}\) The following can be concluded for singly protonated or deprotonated ions (usually observed in MALDI/MS). In the positive ion mode (protonated quasimolecular ion), the most stable structure is the one in which all phosphodiester groups...
are neutral and the proton is located on either G, A, or C. Only for oligothymidylic acids are the proton affinities of the phosphodiester group and the base too similar in value to predict a localization of the proton. It is noteworthy that interactions between phosphate groups and nucleobases are probable, resulting in the transient formation of zwitterions in dependence of the respective proton affinities for both the positive and negative ion mode. Rodgers et al. have calculated the gas-phase acidities of nucleobases in dideoxyribonucleotides and for the phosphodiester group to obtain G (333.4 kcal mol$^{-1}$) $>$ thymine (T) (344.1 kcal mol$^{-1}$) $\approx$ C (345.6 kcal mol$^{-1}$) $>$ A (349.0 kcal mol$^{-1}$) and 329 kcal mol$^{-1}$ for the phosphodiester group.$^{38}$ Hence, in the negative ion mode the charge is expected to be located on one of the phosphodiester groups of the oligonucleotide.

Another characteristic of nucleic acids is the strong affinity towards metal ions. Binding sites are the oxygen...
and nitrogen atoms in the nucleobases and, to a lesser extent, the phosphate and sugar moieties. The importance of metal binding of nucleic acids in vivo lies in the specific interaction with proteins and in the stabilization of the secondary structure. However, this property affects the quality of the mass spectra. Heterogeneous cation attachment, such as the ubiquitous Na⁺ and K⁺, decreases sensitivity, resolution, and mass accuracy. Instead of just the protonated/deprotonated quasimolecular ion, the total ion current (TIC) is distributed over a multitude of ion species. As the mass differences between these different ions are relatively small, the separation of neighboring signals becomes increasingly difficult with increasing analyte mass until only the envelope can be resolved. Owing to the higher resolution of quadrupole analyzers (in the case of the detection of multiply charged larger analytes) when coupled to ESI sources, this effect is less pronounced than it is for the singly charged MALDI ions in the time-of-flight (TOF) analyzer of MALDI instruments. However, impurities are often displaced from the crystalline rim of the sample to the microcrystalline center in MALDI sample preparations (purification by crystallization). ESI lacks this inherent purification mechanism. Moreover, ESI generates predominantly multiply charged ions. Therefore, cations present in the preparation give rise to ion series with the same charge state but a diversity of attached cations. This further complicates the mass spectrum. Therefore, careful sample handling and/or desalting procedures are vital for successful MS analyses.

Improvement in resolution and sensitivity of negative ion ESI mass spectra was first reported by Stults and Marsters. Cation exchange with ammonium acetate via precipitation of the oligonucleotide led to a clear decrease in sodium salt formation for the tested DNA 30-, 48-, and 77-mers (Figure 2).

Desalting is also very beneficial for MALDI/MS. Exchanging metal cations with organic ammonium salts...
turned out to be an effective solution for both ionization techniques. In the gas phase, these ammonium salts release ammonia, and the oligonucleotides are detected as free acids. This principle has been applied to both ESI and MALDI and to various classes of nucleic acid analytes.\(^\text{27–29,41,42}\)

The purification and preparation depends on the chemical environment and the heterogeneity of the sample. Salts present in only small amounts can be suppressed by additives to the analyte solution (ESI/MS) and also to the MALDI matrix. The addition of ammonium tartrate or citrate to matrices such as 6-aza-2-thiothymine\(^\text{43}\) (ATT), and to a mixture of 2,3,4- and 2,4,6-trihydroxyacetophenone\(^\text{44}\) (THAP) has been shown to increase the analyte ion intensity. It is possible that this effect is due to enhanced ionization of the analyte,\(^\text{44}\) more efficient incorporation into the matrix crystals,\(^\text{45}\) or a reduction of cation attachment.\(^\text{46}\) An elegant way to remove monovalent metal cations is the addition of cation-exchange polymer beads (BioRad\(^\text{4}\), Hercules, CA, USA) loaded with ammonium.\(^\text{47,48}\) Both analyte and matrix solutions can be desalted with these beads. An on-target addition of a small aliquot of cation-exchange beads to the MALDI preparation further eliminates cations introduced from the sample support or from pipette tips.\(^\text{47}\)

It was reported that the addition of trans-1,2-diaminocyclohexane-N,N',N''-tetraacetic acid leads to a successful elimination of divalent cations from tRNAs for ESI/MS\(^\text{49}\) but has only a minor effect for MALDI/MS.\(^\text{50,51}\) Reversed-phase high-performance liquid chromatography (RPHPLC) (section 2.2.) has been used to desalt analyte solutions prior to ESI/MS analysis.\(^\text{52}\) This approach offers advantages for shorter oligonucleotides with their lower precipitation efficiencies. Kussmann et al.\(^\text{53}\) introduced a miniaturized version for a fast sample clean-up. The analyte is concentrated in a column (GelLoader\(^\text{54}\) tip, Eppendorf), packed with only a few microliters of Poros\(^\text{55}\) material (PerSeptive Biosystems, Framingham, MA, USA), washed and then eluted directly onto the MALDI target. For DNA and RNA a triethylammonium acetate buffer, pH 7, with acetonitrile–water was employed.\(^\text{54}\) Similar microcolumns in a pipette tip are now commercially available (Millipore, Bedford, MA, USA).

Whereas fragmentation is less pronounced in ESI/MS, it clearly limits the accessible mass range for UV/MALDI. Although fragmentation occurs at all times during the MALDI/TOF measurement (section 2.4.) it is the metastable decay in the field-free drift tube that impairs routine analyses by peak broadening, loss of signal intensity, and therefore reduced resolution (Figure 3). This is particularly marked in instruments with an ion reflector which must be used for large oligonucleotides in IR/MALDI.

It was found that fragmentation increases with the mass of the analyte and is strongly dependent on base composition and applied matrix–laser wavelength combination.\(^\text{48,55,56}\) Three groups determined the order of nucleobase stability T(U) \(\gg\) C \(\gg\) A, G under MALDI conditions,\(^\text{48,55,57}\) and one group found the order T(U) \(\gg\) A \(\gg\) C, G with A and C reversed.\(^\text{56}\) The following
oligonucleotide stability order was observed: oligouridylic (oligothymidylic) acid > RNA > DNA. The higher stability of RNA relative to DNA can be explained by the balancing effect of the 2'-hydroxyl group on polarization of the N-glycosidic bond, induced by protonation of N7 of the purine bases and N3 of C. It was speculated that the 2'-hydroxyl group may also sterically hinder the base loss. This explanation can be ruled out because nucleic acids containing C-arabinose (with the hydroxyl group in the cis position) were found to exhibit a similar stability.

Base protonation was soon found to be the initial step of ion fragmentation in the positive ion mode, leading to cleavage of the N-glycosidic bond, often followed by backbone cleavage (Figure 4). This figure also gives the fragment assignment by McLuckey et al.

For the negative ions the details of the fragmentation mechanisms are still under discussion. A positional dependence of the protonation of base (charge remote fragmentation) has been suggested. The suppression of fragmentation can be accomplished by modifying either the nucleobase, the sugar, or the phosphodiester moieties. 7-Deaza-purine nucleotides, long employed in gel-electrophoresis, afforded a substantial improvement in ion stability. However, due to the participation of N3 of C in base pairing, the corresponding deaza-C-analog is incompatible with enzymatic reactions. It was shown that, at least for mixed-sequence 4-mers, the loss of C is comparable in magnitude to the loss of A and G. Therefore, the stabilization of this base is required as well.

Exchange of the sugar moiety for arabinose and 2'-fluorine modification of ribose have also been reported. Unfortunately, the combination of these modifications with enzymatic reactions turned out to be problematic. Alkylation of the phosphate backbone...
to reduce an interaction of the acidic protons with the bases was demonstrated to be effective for shorter oligonucleotides. The efficiency of this approach to longer oligomers remains to be demonstrated. The choice of the matrix also has a strong influence on the fragmentation of nucleic acids under MALDI conditions. Since its introduction by Wu et al., 3-HPA is the matrix of choice for MALDI mass spectrometric measurements of DNA and RNA because of the limited prompt and metastable fragmentation observed with this matrix. Some prompt fragmentation was shown to take place for this matrix, but fragment ions are not detected because further serial cleavages occur leading finally to low-mass fragments. A few other matrices, such as ATT and several di- and THAPs, have found to be useful for special cases of nucleic acid analysis. It is fair to state, however, that metastable decay remains the main problem for UV/MALDI/MS of nucleic acids.

1.2 General Characteristics of Mass Spectra

DNA and RNA are detected as protonated or deprotonated quasimolecular ions in MALDI/MS. Generally, singly charged ions \([M \pm H]^+/−\) constitute the base peak in MALDI mass spectra, although multiply charged ions \([M \pm nH]^{n+/−}\) and unspecific oligomers (singly and multiply charged, \([nM \pm nH]^{n+/−}\)) are observed. The occurrence of multiply charged ions is more pronounced in the negative ion mode. For most matrices the negative ion mode yields higher signal intensities, with the exception of 3-HPA where the signal intensities are comparable for both ion modes. Matrix signals often dominate the low-mass range of the spectrum, increasing in mass and intensity with the applied laser fluence. A characteristic of ESI is the generation of multiply charged ions. As a rule of thumb, about one charge is present per 1000 Da of ion mass and, therefore, the mass spectrum of every single compound consists of several signals reflecting different charge states of the analyte. However, the charge distribution is strongly dependent on the molecular mass of the analyte, the solvents used, and the instrumental parameters. ESI mass spectra are commonly deconvoluted to determine the peak shape of the equivalent singly charged ion and the molecular weight. In combination with high-performance liquid chromatography (HPLC) the display of the TIC versus the retention time yields a chromatogram of the sample. Each signal of this total ion chromatogram usually consists of several mass spectra depending on the scanning time of the instrument (see Figure 7). In ESI/MS the negative ion mode generally provides higher signal intensities than the positive mode.

2 APPLICATIONS

The accessible mass range, sensitivity, and resolution determine the usefulness of MS in competition with other analytical techniques. The continuing improvements of these parameters have made MS of nucleic acids a widely used tool for a broad range of applications. In addition to accurate mass determination sequencing of polynucleotides, clinical and forensic diagnostics and the analysis of biologically relevant noncovalent complexes have become feasible. Sensitivity has been increased to the subfemtomole level using miniaturized sample preparation techniques. Resolution has made a great leap forward with the implementation of delayed ion extraction (DE) in MALDI/TOF/MS. For DNA up to about 50 nucleotides in length, enhanced resolution has been demonstrated. In addition to better instrumental resolving power, DE leads to a reduced fragmentation in the initial field-free expansion of the generated plume. This further contributes to an increased mass accuracy and sensitivity. 

2.1 Mass Range

In MALDI/MS, fragmentation of the analyte and cation attachment are the main factors limiting both mass range and resolution. Reduced efficiency of ionization and detection may also hamper the analysis of large molecules. Nevertheless, the analysis of DNA up to 50 nucleotides in length by UV/MALDI/MS with a resolution of approximately 1000 FWHM (full-width at half-maximum) for this mass range has become routine. For DNA exceeding 80 nucleotides the resolution quickly decreases to 60–20 FWHM. The detection of a 461-mer in vitro transcript was reported by Kirpekar et al. after removal of the 5' phosphate groups with calf intestine phosphatase to increase homogeneity and sensitivity. The investigation of double-stranded DNA (dsDNA) exceeding 200 base pairs (bps), generated by restriction enzymes from plasmid DNA, was reported by Bai et al. The sample was prepared on a Nafion membrane with 3-HPA as the matrix. Liu and colleagues coated the sample support with nitrocellulose (NC) and observed an improvement in the analysis of complex dsDNA mixtures with up to 622 bp using a 4:1 molar ratio of 3-HPA and PA (picolinic acid). Furthermore, the detection of up to 500-mer ssDNA (single-stranded DNA) PCR (polymerase chain reaction) products was reported by Tang et al. with mixtures of 3-HPA and PA on a standard sample support. Ross and Belgrader were able to detect a ssDNA 268-mer PCR product with a mixture of 3-HPA and PA in a solution of ammonium citrate and acetonitrile. The key to this successful analysis was the purification and isolation of a
single-stranded PCR product by affinity capture using streptavidin-coated magnetic beads. In most cases only the dehybridized single strands are detected under the given MALDI conditions. Most of the individual strands of dsDNA exhibit only a small mass difference. For higher-mass analytes, this mass difference cannot be resolved further, leading to additional peak broadening. To avoid the severe fragmentation observed for larger oligonucleotides in UV/MALDI, Berkenkamp et al. used IR/MALDI with glycerol as the matrix and an Er/YAG laser with a wavelength of 2.94 µm for the analysis of restriction enzyme digests of plasmid DNA of more than 2000 nucleotides. They observed a dramatically lower fragmentation under these conditions. However, so far mass resolution is limited to only 50–100 throughout the mass range representing about 100 to 1500 nucleotides.

Using ESI, the detection of intact highly charged DNA ions in the megadalton range has been demonstrated. Ions exceeding 1 MDa were detected by Fourier transform ion cyclotron resonance mass spectrometry (FTICR/MS) and a TOF analyzer with a charge detector. Extremely high values for the mass resolution have been obtained by FTICR/MS, but the heterogeneity of the charge states of the trapped ion population complicates the interpretation of the spectra. Chen et al. succeeded in the detection of coliphage T4 DNA ions by FTICR/MS. In this case the charge state of an individual highly charged anion could be determined by analyzing the decrease of the charge state over a given time interval. For the T4 DNA a charge state of 31 530 and a mass of 90.9 × 10^6 Da could be determined in this manner with a precision of 10%. In a subsequent work Cheng et al. reported the detection of pGEM-5S plasmid DNA. Determining a mass of 1.5 MDa (calculated 1.946 MDa) these workers reduced the uncertainty to ca. 3%. Nonetheless, the uncertainty in determining the charge state and hence the molecular weight remains a problem in the analysis of large nucleic acids by ESI/FTICR/MS. Fuerstenau and Benner generated ions from plasmid and phage DNA ranging from 2.8 to 31 MDa by ESI. The analyzer was a TOF mass spectrometer equipped with a novel charge-sensitive detector that allows for an independent determination of the m/z ratio and the charge of the ion. With this detector (a Faraday cage-like metal tube) the image charge signal of an individual ion is amplified by a low-noise charge-sensitive amplifier and the m/z corresponds to the time that the ion needs to pass the detector tube. Again, the uncertainty in determining the charge states decreases the mass accuracy. Refining this technique has led to the development of a gated electrostatic ion trap, in which an individual ion is trapped between two plates and, therefore, traverses the detector tube.

**Figure 6** Histogram of the average mass obtained from each of 549 pBR322 trapped ions. (Reprinted from W.H. Benner, *Anal. Chem.*, 69, 4162–4168 (1997) with permission from American Chemical Society, Copyright 1997.)
several times. The single measurements of charge state and $m/z$ can be averaged and hence reduce the signal-to-noise ratio compared with a single measurement. Figure 6 shows the histogram of the average mass acquired from 549 trapped pBR322 plasmid ions. The signal at mass 2.88 Da corresponds to the sodiated (protonated) pBR322 ion and the signal at 5.85 Da to the dimer.

2.2 Mixture Analysis and Combination of Mass Spectrometry with Separation Techniques

The ability to analyze mixtures is an important feature because many samples, such as those from a Sanger reaction, contain a number of individual species of different mass. Furthermore, the impurities of real-life samples and the heterogeneity (e.g. different modifications) of the sample can be determined. One important point for the analysis of mixtures in which the analytes are present in different concentrations is the dynamic range. This parameter is dependent on the analyzer used and describes the concentration difference between two components when both are still detectable – one signal distinguishable from the background noise (e.g. a signal-to-noise ratio greater than 2) and the other signal near saturation. Another critical point in mixture analyses with MALDI is that higher-mass analytes often require higher desorption laser fluxes. At these fluxes, the resolution of lower-mass analyte signals may already be lower than that attainable for the pure low-mass compounds.

As mentioned before, the difficulty in analyzing larger molecules may have its cause in a higher degree of fragmentation and a decreased detection efficiency. Larger molecules may also be in competition with smaller molecules for the charges. For an easy interpretation of the spectra it is beneficial if every component has only one major charge state, i.e. one peak in the MALDI mass spectrum. Therefore, the positive ion mode should be preferred for MALDI/MS, particularly with 3-HPA as the matrix, as in the negative ion mode multiply charged ions are observed to a larger extent. This is also the reason why ESI/MS with its multiply charged ion distributions is inferior to MALDI/MS for mixture analyses if the masses of the mixture components extend over a wide mass range. However, ESI is superior for the analysis of mixtures which vary only slightly in mass, because of its inherently higher-resolution mass analyzers. Therefore, the demand on resolution depends on the expected mass differences between adjacent peaks. An elegant way of performing mixture analysis is online coupling with different separation techniques such as chromatography and electrophoresis. In addition to the separation of molecules which may differ only slightly from each other, the elimination of sample impurities is a great advantage of such combinations. Electrospray is especially suited to the combination with liquid chromatography because the analyte is ionized from solution.

Figure 7 Analysis of synthetic pBR322 oligonucleotides by HPLC/ESI/MS. (a) Total ion chromatogram, (b) raw mass spectrum, (c) deconvoluted mass spectrum. (Reprinted from A. Apffel et al., Anal. Chem., 69, 1320–1325 (1997) with permission from American Chemical Society, Copyright 1997.)
However, the buffers have to be optimized with respect to both the chromatographic separation and the MS ionization steps. An ammonium acetate or triethylammonium acetate–acetonitrile gradient was used in a concentration of 5–10 mM by Bleicher and Bayer. The good compatibility with the ionization was compromised by the low separation efficiency. Apffel et al. introduced a gradient system with 1,1,1,3,3,3-hexafluoro-2-propanol adjusted to pH 7 with triethylamine, which yielded a superior separation resolution and also higher ionization efficiency (Figure 7).

This buffer system was also used by Griffey et al. for the characterization of phosphorothioate (replacement of the nonbridging oxygen of the phosphate backbone by sulfur) oligodeoxynucleotides from in vivo metabolism in pig kidney. The coupling of HPLC to an ESI ion trap made it possible to determine the base compositions of the respective metabolites of the injected phosphorothioate DNA. Sequence information could also be obtained via fragmentation. Thus 3' and 5' exonuclease activity and, presumably, also endonuclease activity as well as the addition of single deoxyribo- and ribonucleotides were observed. For MALDI/MS both off-line and on-line coupling with chromatographic and electrophoretic techniques have been reported. On-line coupling is less common and requires modification of the preparation technique. A detailed discussion on combining MALDI with liquid separation techniques is available.

2.3 Noncovalent Complexes

An understanding of biomolecular interactions helps in comprehending life on the molecular level. Noncovalent interactions between biomolecules govern all cellular processes. Knowledge of the recognition between proteins and nucleic acids, such as between polymerase and DNA, is of great importance to the understanding of cell division and cell proliferation. The detection of noncovalent complexes using MALDI/MS is not possible with the preparation protocols mentioned so far. This indicates that the choice of matrix and preparation are of vital importance. A general characteristic of MALDI mass spectra is the frequent observation of the most probable gas-phase-generated unspecific analyte oligomers. These oligomer signals are generally much weaker than the quasimolecular ion peaks. Furthermore, their intensities decrease with increasing degree of oligomerization. Although these characteristics can aid in distinguishing specific complexes from unspecific adducts, great care has to be taken to verify the nature of noncovalent complexes, e.g. by competition experiments and careful attention to the relative signal intensities.

The first noncovalent nucleic acid complex observed by MALDI was reported by Lecchi and Pannell. They succeeded in detection of the EcoR1 adaptor double-stranded 16/12-mer in addition to the single strands in 1995 using ATT as the matrix. No unspecific oligomerization was observed. Control experiments with 3-HPA and THAP showed no signal for the double strand (Figure 8).

Digestion with nuclease S1, which is much more active in cleaving ssDNA than dsDNA, was used to show that the single strands, as well as the duplex, originated from the original sample rather than being generated by the MALDI process. The same authors reported later that those chemicals having a stabilizing effect on oligonucleotide structure in solution also improve the detection of specific complexes. Thus, calcium as well as spermidine substantially enhanced the detection of a dsDNA. (Adapted from P. Lecchi and L.K. Pannell, J. Am. Soc. Mass Spectrom., 6, 972–975 (1995) with permission from Elsevier Science, Copyright 1995 by American Society for Mass Spectrometry.)

Figure 8 MALDI spectrum of EcoR1 12/16 adapter with ATT as the matrix. The DNA dimer region with 2,4,6-THAP as the matrix is shown for comparison at a 20-fold expansion in the inset. Only peaks from the single-stranded oligonucleotides were observed with 2,4,6-THAP. The ion at 8609.3 (calculated value 8606.6) in the ATT spectrum represents the detection of dsDNA. (Adapted from P. Lecchi and L.K. Pannell, J. Am. Soc. Mass Spectrom., 6, 972–975 (1995) with permission from Elsevier Science, Copyright 1995 by American Society for Mass Spectrometry.)
complex. Further addition of a destabilizing agent such as succinic acid (acidic denaturation) hindered detection of the complex. The largest dsDNA detected was a 1.05 kbp fragment of about 645 kDa in mass. The authors stated that the quality of spectra with fragments exceeding 1 kbp of length is significantly reduced. Figure 9 shows the IR/MALDI reflection TOF mass spectrum of a mixture of dsDNA generated by the digestion of the plasmid pBluescript-KS+ with the enzymes BglII and RsaI using glycerol/ammonium acetate matrix.

As an example of a biologically relevant protein–nucleic acid complex, Gruic-Sovulj et al. reported the specificity of the complexes was verified by competition experiments testing both tRNAs against a given synthetas. In that case, the specificity of the complexes was verified by competition experiments testing both tRNAs against a given synthetas.

Because of the gentleness of the desorption ESI lends itself even more than MALDI to the detection of noncovalent associations. Instrumental parameters such as temperature and declustering voltage of the ion source as well as the chemical environment of the sample have a great influence on the success of the analysis. As nonspecific complexes have also been reported for the occurrence of Watson–Crick bps of the dsDNA since 1993. Instrumental parameters such as temperature and declustering voltage of the ion source as well as the chemical environment of the sample have a great influence on the success of the analysis.

Moreover, a correlation between the gas-phase dissociation activation energies and the dimerization enthalpies in solution was observed. Interaction between dsDNA and metal ions as well as drugs have also been investigated and collision-induced dissociation (CID) of the complexes was found to be a facile approach with which to verify the correctness of the noncovalent binding. Cheng et al. determined the binding stoichiometry of gene V protein from bacteriophage f1 with oligonucleotides through competition experiments. Oligonucleotides with 16 nucleotides showed a stoichiometry of 4:1 (protein monomer/oligonucleotide), whereas oligonucleotides with 15 nucleotides and lower had a stoichiometry of 2:1. Control experiments at low pH values (acid-induced denaturation) displayed no complex formation, whereas the complexes were unaffected by an increase of the interface capillary temperature of the instrument. These results agreed with those obtained by size-exclusion chromatography. Furthermore, competition experiments involving the transcription factor PU.1 DNA binding domain (PU.1-DBD) and dsDNA.

**Figure 9** IR/MALDI reflectron TOF mass spectrum of a mixture of dsDNA fragments recorded from a glycerol/ammonium acetate matrix. The sample was generated by digestion of the plasmid pBluescript-KS+ with the restriction enzymes BglII and RsaI. (Reprinted from F. Kirpekar et al., *Anal. Chem.*, 71(13), 2334–2339 (1999) with permission from American Chemical Society. Copyright 1999.)

**Figure 10** ESI/MS spectra of PU.1-DBD and mixtures of DNA in 10 mM ammonium acetate (pH 7.0) acquired on a fourier transform ion cyclotron resonance (FTICR) instrument. Mixtures contain (a) PU.1-DBD (5 μM), 17 bp DNA (15 μM), and 19 bp DNA (20 μM); (b) PU.1-DBD (3 μM), 17 bp DNA (10 μM); and 19 bp DNA (200 μM). Abbreviations in the spectra: D = dsDNA, B = heavy strand of dsDNA, and w = wild-type and m = mutant-type DNA sequences. (Reprinted from X. Cheng et al., *Anal. Biochem.*, 239, 35–40 (1996) with permission from Academic Press. Copyright 1996.)
containing (17 bp, wild type) or missing (19 bp, mutant) the recognition motif revealed the specificity of the complex.\textsuperscript{114} Even for a 20-fold excess of the dsDNA lacking the binding motif only the specific complex was detected (Figure 10).

The stability of a specific noncovalent tryptophan repressor-DNA-complex was shown by Potier et al.\textsuperscript{115} with CID. Dissociation of this protein-dimer/operator DNA complex could be achieved only under conditions which also cleaved covalent bonds, probably depurinating the DNA.

These examples for the detection of noncovalent complexes illustrate that MS is a valuable method as long as the specificity of the complex can be verified and the complex reflects the true solution structure. Information on binding stoichiometry, dissociation constants,\textsuperscript{116} base composition, and even structural information can be obtained in addition to proof of the existence of the complex itself.\textsuperscript{117–119}

2.4 Sequencing Approaches

Because of the accessible mass range and the decrease in resolution with increasing length of nucleic acids, the available mass spectrometric sequencing techniques present no challenge to the conventional techniques used, e.g. in the human genome project. Nevertheless, MS is an accurate, rapid, and sensitive tool ideally suited for sequencing shorter nucleic acids. Consequently, MS sequencing holds great promise in the fields of clinical diagnostics, forensics, paternity analysis, livestock breeding, plant cultivation, and cell line typing. One of the advantages of MS over gel-based Sanger sequencing lies in the fact that the mass is an intrinsic property of the molecule rather than an extrinsic one such as electrophoretic mobility. Furthermore, the mass can provide evidence for the occurrence of modifications in the analyte and an accurate mass measurement allows for the determination of base composition, as was shown by Pomerantz et al.\textsuperscript{120} Aaserud et al.\textsuperscript{121} demonstrated that analyzing dsDNA with ESI/FTICR defines or restricts the bp composition up to 600 bp. Sequencing strategies can be divided in three categories: sequencing by process-induced fragmentation, sequencing via chemically generated fragments, and sequencing using enzymatic reactions.

2.4.1 Sequencing with Process-induced Fragmentation

Although fragmentation hampers MALDI analysis of nucleic acids to a great extent it can also be capitalized on to gain sequence information when the fragmentation is controlled. The emphasis lies on the term controlled. The desired cleavage pattern should be a consecutive disjunction of the nucleotide constituents at specific bonds. An additional, but less intense, loss of bases and phosphate groups can help to characterize and locate possible modification sites. However, multiple base losses and predominance of certain nucleotide cleavages over others will only disturb or even prevent sequence determination. It has to be kept in mind that the impact of fragmentation on the mass spectrum depends on the decay time in relation to the instrumentally determined time frame for the analysis. Depending on the mass, the flight time of an ion in a TOF mass spectrometer is in the microsecond to low millisecond range. This dependence of the decay time constant is particularly pronounced for TOF analyzers. Therefore, a short description of their relevant properties is given here. More detailed information about mass analyzers is given in the instrumentation section of this encyclopedia.

2.4.1.1 Decay Time in Regions where the Electric Field is Nonzero

These are primarily the region of acceleration right in the source and in the ion reflector. As a rule of thumb, fragments generated in these regions are distributed and are therefore unpredictable in mass. For TOF instruments with static ion extraction a fragment is termed prompt if its decay time constant is comparable to the generation time of its parent ion. Such fragment ions will encounter the full acceleration voltage and are detected at their correct \textit{m/z} value in the mass spectrum. Ions that fragment shortly after the generation of the parent ions (fast fragments) up to the time until the parent ion leaves the accelerating region have an energy deficit and are, therefore, not detected at their correct mass in the spectrum. Ions resulting from this type of fragmentation are not suited for sequencing, because the true fragment masses cannot be determined.

2.4.1.2 Decay in Regions where the Electrical Field is Zero

With the implementation of DE, ions with longer decay time constants can, however, provide valuable sequence information.\textsuperscript{122} Fragments, generated during the delay time of typically a few hundred nanoseconds are detected at their true masses in the spectrum. These ions are called in-source decay (ISD) fragments. Metastable fragmentation occurs in the field-free drift tube of the TOF analyzer, i.e. after the parent ion has left the acceleration region (post-source decay (PSD)). These fragments continue to fly with very nearly the same velocity as the parent ion and are detected together with the parent ions in instruments with a linear geometry. This is also true if the mass difference compared to the parent ion is small enough for the associated energy deficit to be compensated by a reflectron. (A reflectron functions as an ion mirror and is used for compensating kinetic energy distributions of the generated ions.) With increasing mass loss, metastable decay
fragments manifest themselves in the spectra recorded with a reflector TOF as a shoulder on the low-mass side of the peak. This type of fragmentation can be used for sequencing, if the deceleration potential of the reflector is lowered in steps to display a small mass window of fragments whose mass can be determined with sufficient accuracy (PSD spectrum\(^{(123)}\)).

Process-induced fragmentation has the advantage that no additional steps of preparation and sample handling are required. Nordhoff et al. have reported direct mass spectrometric sequencing of DNA up to 21 bases by IR/MALDI (Er/YAG laser, 2.94 µm) in the negative ion mode\(^{(60)}\). With low-picomole sample amounts and the matrix succinic acid three series of sequence-specific prompt fragmentations were observed (Figure 11).

In contrast to the explanation given by Grotjahn et al.\(^{(19)}\) Nordhoff et al. found that the 80 Da mass shift is not an HPO\(_3\)^{−}\ artifact, but originates from an additional sugar moiety of the 3′ terminal phosphate group of d. Loss of a base is followed by cleavage of the 3′ C—O bond and results in fragments w and (a-B). Further loss of the furan moiety from (a-B) leads to d (see Figure 4). This sort of analysis is impeded by a relatively low shot-to-shot reproducibility, the competing high rate of metastable decay of the DNA, and the lack of fragmentation at T sites. Prompt fragmentation providing sequence information for DNA was also investigated in the negative ion mode.

**Figure 12** The MALDI spectrum of negative ions for a 28-mer 5′-CTT GGT AAA CAA ATT CTT GCT CGT TGA T-3′ oligonucleotide and its simulated spectrum of y-fragments ions. (Reprinted from Y.E. Zhu et al., *Rapid Commun. Mass Spectrom.*, 11, 897–903 (1997) with permission from John Wiley & Sons Limited, Copyright 1997.)

with a UV laser (N\(_2\)) emitting at 337 nm\(^{(124)}\). Sequencing of DNA up to 35 nucleotides was demonstrated with the matrix systems 2-aminobenzoic acid and 2,4,6-THAP, both with dibasic ammonium citrate. Figure 12 shows the mass spectrum for a DNA 28-mer.

The full sequence can be read from the 5′ terminus, except for the last three nucleotides which are buried in the matrix background. Interestingly only the 5′ terminal w and y fragments appear in the spectrum. An additional loss of single bases was at least seen for a DNA 10-mer. Juhasz et al.\(^{(75)}\) applied DE for sequencing DNA in the low-picomole range based on ISD in the negative ion mode. Whereas the combination of 3-HPA with an N\(_2\) laser emitting at 337 nm showed no fragment ions of a DNA 11-mer, an ion series consisting of w, d, and also y ions was observed with PA at a laser wavelength of 266 nm (frequency quadruplet neodymium/yttrium–aluminum–garnet (Nd/YAG) laser). No a ions or base losses were detected. The w ions provided complete sequence information. Wang et al.\(^{(125)}\) also applied ISD to sequence modified oligonucleotides with a combination matrix of 3-HPA and N-(3-indolylacetyl)-l-leucine at higher laser irradiances, significantly above the ion detection threshold. Sample amounts prepared were in the 30–160 pmol range. The fragmentation pattern of several modified DNAs composed of among others phosphorothioate and methylphosphonate (replacement of the hydroxyl group in the phosphate backbone by a methyl group) linkages, 2′-methoxy groups and DNA/RNA chimeras contain several different ion types for both ion polarities. The complete w series was observed accompanied by a, (a-B), and d ions and, at lower abundance, b, c, d, and z ions (Figure 13).
For these samples no fragments were detected without DE, even at higher laser irradiances. An explanation given by the authors for the occurrence of a ions is the high density of matrix ions, radicals, neutrals, and analyte in the generated plume. The absence of this ion type in the measurements of Juhasz et al. may be attributed to the fact that, in addition to the different matrix–wavelength combination, much lower sample amounts were prepared.

Sequencing by PSD can be achieved routinely for peptides and small proteins, but this method is more difficult to apply to oligonucleotides. The first PSD spectra were reported by Kirsch et al., representing a DNA 5-mer analyzed in the positive ion mode. The spectrum is complicated by multiple base losses from the parent ion as well as from the fragments. As was observed for prompt fragmentation, T sites in the molecule are only cleaved with very low intensities. Wang
et al.\(^{64}\) demonstrated the feasibility of PSD/MALDI to differentiate between structural isomers in the negative ion mode. Figure 14 illustrates the distinction between dTAGT and dTGAT by different w\(_2\) and (a\(_3\)-B\(_3\)) ions.

PSD analyses of modified oligonucleotides have also been reported.\(^{128,129}\) The coupling of MALDI to FTICR to investigate process-induced fragmentation of oligodeoxynucleotides with and without modifications have been reported by Buchanan and colleagues.\(^{130–133}\) Unfortunately the lower fragment masses dominate these mass spectra.\(^{133}\)

Under standard ionization conditions fragmentation is less prominent for ESI. However, fragmentation can be induced in the atmospheric pressure region between the ESI spray needle and the skimmer orifice (nozzle skimmer (NS) dissociation),\(^{134}\) by collisional activation with inert gas molecules (i.e. by CID)\(^{135}\) or by irradiation of the ions with an IR blackbody (or laser), usually from a CO\(_2\) laser source, in the FTICR cell (infrared multiphoton dissociation (IRMPD)).\(^{136}\) Quadrupole ion traps\(^{63,137–139}\) FTICR cells\(^{136,140–142}\) and triple quadrupole instruments\(^{143–145}\) have been used for these investigations. Fragmentation depends on the amount of energy transferred to the analyte. Owing to the higher collision energy in quadrupoles as compared with ion traps, fragmentation is more pronounced in the former, leading to a more complete sequence information. In FTICR instruments, the combined application of NS dissociation, CID, and IRMPD can provide complete sequence information up to 50 nucleotides and extensive fragmentation up to 108 nucleotides.\(^{142}\) Figure 15 shows the spectra obtained with (a) NS dissociation and (b) CID of a DNA 8-mer.

For process-induced fragmentation the sample amount needed is often elevated, which is of concern for biological samples, but usually not for synthetic nucleic acids. The complexity of the mass spectrum and possible isobaric fragments of partially modified oligonucleotides somewhat limits these applications for routine complete sequencing of unknown samples. However, sequence verification of oligonucleotides can easily be performed with these approaches.

### 2.4.2 Sequencing with Chemically and Enzymatically Generated Fragments

Bond cleavage can also be achieved with enzymes or chemical agents added to the sample solution prior to MS analysis. One advantage of chemical over enzymatic cleavage is the less pronounced dependence on the secondary structure of the analyte. Furthermore, modifications of the backbone which lead to resistance against enzymatic degradation can be capitalized on to gain sequence information. Thus methylphosphonate DNA (used in antisense oligonucleotides) is resistant to nuclelease digestions but can be sequenced by chemical means. Keough et al.\(^{146}\) demonstrated the use of synthesis failure sequences for MALDI/MS to verify the identity of the synthetic product. Owing to the nature of the synthesis and the yield of 96–99% per synthesis cycle, a ladder consisting of the specific failure sequences is generated. In a subsequent paper Keough et al. combined failure synthesis analysis with exonuclease digestion and limited alkaline hydrolysis of the methylphosphonate linkages, allowing the complete sequence of a modified 18-mer to be read.\(^{147}\)

Failure sequences allow one to read the sequence from the 5’ terminus of the oligonucleotide, whereas snake venom exonuclease successively cleaves nucleotides from the 3’ end. Sequence information can be completed by alkaline hydrolysis because the methylphosphonate linkages are exclusively susceptible to base-catalyzed hydrolysis. Polo et al.\(^{148}\) demonstrated that the approach to sequence phosphorothioate-containing oligonucleotides with alkylating agents, first presented by Nakamaye et al.\(^{149}\) can be adapted for mass spectrometric analysis – 2-iodoethanol specifically alkylates...
phosphorothioate linkages, and cleavage occurs generating 3' and 5' fragment ladders. Although the complete sequence could be obtained for an all-phosphorothioate DNA 10-mer without being disturbed by the presence of internal fragments, the spectrum quality was poor, particularly the signal-to-noise ratio of the fragments. Limited alkaline hydrolysis was used by Hahner et al.\(^\text{150}\) in combination with endonuclease cleavage of RNA to deduce sequence information. Alkaline hydrolysis alone provided nearly the complete sequence information for...
Figure 16  Comparison of partial 3' → 5' and 5' → 3' exonuclease digestions analyzed by DE/MALDI. The time of each digestion is indicated. Both peak 1G in (a) and 33A in (b) correspond to the undigested 33-mer of sequence 5'-GCC AGG GTT TTC CCA GTC ACG ATG CAG AAT TCA. (a) 5' → 3' digestion with calf spleen phosphodiesterase. (b) 3' → 5' digestion with snake venom phosphodiesterase. (Adapted from I.P. Smirnov et al., Anal. Biochem., 238, 19–25 (1996) with permission from Academic Press, Copyright 1996.)

A synthetic RNA 25-mer. Because of the mass difference of only 1 Da between U and C, differentiating between them is difficult and a high resolution is vital, especially for large specimens. The use of base-specific endonucleases helped to solve this problem, but enzymatic specificity and efficiency may be compromised under the conditions used for MALDI analysis.\(^{52}\) Tolson and Nicholson\(^{151}\) applied hydrazine and aniline
as chemical agents for the specific cleavage of uridine sites in RNA to verify the sequence information obtained by exonuclease digestion. McCloskey and colleagues developed an ESI/MS-based approach that involves cleavage with base-specific endonucleases to locate and determine modifications in RNA. Major contributions to the localization and characterization of RNA modifications were given by the McCloskey and Crain group. Non-specific endonucleases were used by Linscheid and colleagues in combination with capillary zone electrophoresis ESI to determine the sites of styrene adducts. The use of exonuclease-generated sequence ladders with subsequent mass spectrometric analysis was first reported by Pielies et al. involving the phosphodiesterase from snake venom and calf spleen (the latter cleaves specifically from the 5’ terminus) and was soon adapted by others. Smirnov et al. optimized the cleavage conditions specifically for the MALDI preparation and presented excellent quality spectra containing the complete sequence information of a DNA 33-mer (Figure 16).

The analysis of exonuclease-generated sequence ladders with ESI was shown by Limbach et al. by immobilizing the PCR product on solid phases and demonstrating the superiority of MALDI/MS in exploring the murine PPAR5 exon 1 PCR fragment. Kirpekar et al. analyzed clinical heterozygously expressed samples and demonstrated the superiority of MALDI/MS in the mass spectrum. In this investigation an unexpected nucleotide polymerization event was detected at the third position. Misincorporation of dGMP and also dCMP – clearly seen in the ddC reaction – at this position leads to termination whereas the strong signal in the ddT spectrum reveals the presence of T at this position. False and specific termination can be distinguished from each other as the mass difference of two adjacent signals in the mass spectrum provides information about the type of nucleotide. Doublets (mass difference 16 Da) can be observed in the respective mass spectrum as the incorrect product carries a deoxynucleotide rather than the dideoxynucleotide at the terminus. Further advantages of coupling Sanger sequencing of rather short templates with MS are the ability to obtain sequence information in close proximity to the primer, the high speed of analysis and the ability for automation in process lines. Köster et al. captured biotinylated DNA templates with streptavidin-coated magnetic beads and performed primer extension terminated with the respective ddNTPs in four reactions for sequencing up to 63 nucleotides. Only the primer-extended products are detected as the ionization–desorption process does not disrupt the biotin–streptavidin linkage.
2.5 Clinical Diagnostics with Mass Spectrometry

Clinical diagnostics do not necessarily depend on complete sequencing. Various rapid screening methods for mutations and polymorphisms have been developed which can be easily performed by MS. Multiplexing greatly enhances the amount of information that can be gained in a single measurement. A classical approach to screen for mutations in a given DNA strand is a restriction endonuclease digest followed by gel-electrophoretic separation of the generated fragments, in which differences of the fragment length and/or the pattern are indicators of mutations (restriction fragment length polymorphism RFLP). Lubman and colleagues have adapted restriction endonuclease cleavage of PCR-amplified DNA with subsequent detection by MALDI/MS to screen buccal cell DNA up to 426bp for polymorphisms. The cystic fibrosis gene was the target for Ch'ang et al. who screened the DNA of 30 individuals for the most common ΔF508 deletion using MALDI/MS. Another strategy pursued by this group involves PCR amplification of the DNA of interest (cystic fibrosis transmembrane conductance regulator, CTFR gene) with two pairs of primers, one pair for the wild-type DNA and one pair for the mutant DNA, thus leading to different PCR products for the homozygote wild type, heterozygote, and homozygote mutant patients. Jurinke et al. screened blood bank samples for hepatitis B virus (HBV) DNA by amplifying its encoding core antigen (HBc) with PCR. Biotinylation of one of the primers enabled purification after immobilization on streptavidin-coated magnetic beads and detection of the complementary strand after hybridization with MALDI/MS. The sensitivity was enhanced in following work with the aid of nested PCR, in which HBV DNA was detected in 11 out of 21 sera of patients supposedly cured (positive isolated anti-HBc). The same group reported a rapid screening method for known mutation sites by primer oligo base extension (PROBE) and MALDI/MS. This strategy relies on the annealing of a specific primer, or in a biplex reaction of two primers, downstream of the suspected mutation site and primer extension, in which one of the four deoxynucleotides is completely substituted by its dideoxy analog. Mutations manifest themselves through the length of the PROBE product, and the number of signals are indicators of the heterozygosity of the allele. Performing PROBE as a temperature-cycled rather than an isothermal assay leads to an enhancement in sensitivity. Braun et al. demonstrated that the PROBE reaction is also suited for the analysis of microsatellites by MS if the repeat unit does not consist of all four nucleotides. Investigating the number of AluVpA microsatellite repeat units of the five members of a given family by digestion of the respective PCR product with a restriction endonuclease and subsequent separation by gel electrophoresis showed 13 and 12 repeat units for the mother, 11 and

Biotechnol., 16, 1347–1351 (1998) with permission from Nature America, Copyright 1998.)

8 for the father, and combinations thereof for the three children, whereas the PROBE reaction in combination with MALDI/MS revealed second-site mutations within the 13 repeat unit. It was shown by sequence analysis that transitions of T to C in the second and T to G in the eighth repeat lead to a truncated version of the 13 repeat when the PROBE reaction is performed with ddGTP (Figure 18)
Since its invention PROBE assay has found applications in the analysis of more than 100 mutations/polymorphisms of human genes.\(^{(70,177)}\)

Another rapid screening method for the detection of single nucleotide polymorphisms, nucleotide deletion, insertion, and substitution is the pinpoint assay.\(^{(178)}\) This approach uses the annealing of specific primers downstream of the putative mutation site/polymorphic region. The analytic information is contained in the mass shift of the single base-extended primer. The assay has a high potential for multiplexing. Figure 19 shows the 12-fold multiplex spectrum of loci listed in the table.

Wunschel et al.\(^{(179)}\) used ESI/FTICR analysis for the detection of heterogeneity in the highly conserved 16/23S rDNA interspacing region from Bacillus cereus 6464. Interestingly, more PCR-amplified double-strands were detected than expected. The accurate mass measurement of the single-strands revealed a missing T in the coding and a missing A in the noncoding strand, in addition to the predicted masses. Laken et al.\(^{(180)}\) analyzed genetic variants of PCR-amplified DNA with ESI ion trap MS coupled to HPLC. The key of this approach, called SOMA (short oligonucleotide mass analysis), is the implantation of an artificial restriction endonuclease type IIS recognition site within the employed primer pair, hence determining the length of the amplified DNA and the length of the digest fragments (7–20 nucleotides) which mirror the genetic variation. The cleavage of the PCR-amplified DNA with restriction endonucleases ensures that the fragment length is amenable for ion trap MS. Figure 20 describes the investigation of common polymorphisms in the APC gene at the codons 485, 545, and 1756.

The simultaneous detection of the three different codons after combining the separate PCR reactions and digests illustrates the ability to analyze multiplexed reactions. Furthermore, the ion trap can be used to analyze induced fragmentation of the single DNA stretches, providing even more information in cases of isobaric single strands.

Performing diagnostics with MALDI/MS has the advantage that the analysis can be easily combined with computer technology, allowing large-scale diagnostics using parallel processing, whereas ESI is superior when analyzing larger analytes.

### 2.6 Conclusions

MS is only a recent addition to the plethora of analytical techniques in nucleic acid analysis. Its contributions to the fields of biology, biochemistry, biomedicine, and biotechnology will, no doubt, increase substantially in the near future as new applications and analytical procedures are developed.

### ACKNOWLEDGMENTS

We would like to thank Hans C. Lüdemann, Finn Kirpekar and Kerstin Strupat for a critical reading of the manuscript and helpful discussions.

1 Introduction

Nuclear magnetic resonance (NMR) is one of the most important and widely used techniques for studying nucleic acid structure. With modern techniques, including isotope labeling and multidimensional spectroscopy, structures of large molecules – nucleic acids alone or in complexes, for example with proteins or ligands – can be determined. Here is given an overview of experimental NMR methods for nucleic acids studies, complemented by illustrative examples of DNA, RNA and PNA structures.

1 INTRODUCTION

NMR is one of the most important and widely used techniques for studying nucleic acid structure. NMR offers the advantage of permitting high-resolution studies of molecules in solution, and thus of manipulating conditions such as concentration of various ions and ligands, temperature and pH. Although the number of NMR spectra of nucleic acids acquired in solid phase is growing rapidly, the vast majority of experiments are still carried out in aqueous solution. This review will therefore focus on nucleic acid structure in solution as studied by NMR methods. This subject has previously been carefully reviewed, for example by Van de Ven and Hilbers and by Patel et al.

There has been a hand-in-hand development of increasingly more affordable methods of preparing isotope-labeled oligonucleotides, both DNA and RNA, and new pulse sequences taking advantage of their incorporation. Many of these pulse sequences are tailored to detect single correlation pathways that are instrumental in making correct assignments of a spectrum. To cover an inclusive menu of experiments now available would be formidable, task, such a list could not be condensed into the format of this article, and even if it could, would quickly become outdated. The aim here is instead to give a general introduction to available techniques complemented by illustrative examples of a few representative structures. These structures should give an idea of the range of problems now tractable by NMR and indicate strategies for solving them.

2 NUCLEAR MAGNETIC RESONANCE AND NUCLEIC ACIDS

Nucleic acids are structurally versatile molecules (for detailed descriptions of nucleic acids nomenclature and parameterization, please refer to Saenger and Lu and Olson). With DNA this is manifested as a multitude of tertiary structure motifs seen primarily as a variety of multistranded complexes. RNA is also highly variable at a secondary structure level, with alternate basepairing interactions and intricate folding topologies. For structural information about nucleic acids to be meaningful, a high degree of accuracy is therefore required and structural information derived from NMR experiments will often not be conclusive unless the spectra of a molecule can be unambiguously interpreted. Techniques have been developed that have considerably widened the scope of NMR studies. In particular, improved and more affordable isotope-labeling methods combined with higher field instrumentation and multidimensional pulse sequences have permitted structure studies of nucleic acids as long as 40 nucleotides, even in complexes with proteins, possible by NMR.

2.1 Spectral Properties

2.1.1 DNA

The proton NMR spectrum of DNA (Figure 1) is usually nicely distributed between 0 and 15 ppm. For molecules with a relatively low degree of complexity, such as a duplex, it is often possible to carry out assignments...
unambiguously for the majority of the protons in an unlabeled sample based solely on two-dimensional (2D) experiments. Typical proton spectra of a DNA duplex in D$_2$O and H$_2$O are shown in Figure 2. Protons that do not exchange at a significant rate with the solvent generally appear in the region between 0.5 and 8.5 ppm (Figure 2a). Labile protons, such as the amino and imino protons are usually observed between 6–10 ppm and 11–15 ppm, respectively (Figure 2b).

Figure 1 Schematic structure of PNA, DNA and RNA. \( b = \) base.

Assignment of the nonexchangeable protons – the aromatic H6/H8, H2, H5 and the methyl and sugar protons of a regular B-form DNA duplex – can usually be done from NOESY (nuclear Overhauser spectroscopy) and COSY (correlation spectroscopy) data recorded in D$_2$O, while the exchangeable protons can be assigned from H$_2$O NOESY spectra. Sometimes data acquired at a few different temperatures are helpful in overcoming assignment problems caused by spectral overlap.

2.1.2 RNA

In ribonucleotides the 2'-hydroxy group (Figure 1) causes the H2' resonances to shift downfield so that they overlap with the H3' signals. The H5 resonances of the uracil bases appear in the 5.0–6.0 ppm region along with their cytosine analogs. Because of overlap in the sugar proton region, complete assignment of an RNA oligonucleotide may be difficult without the use of isotope labeling and a number of multidimensional experiments. Strategies for this are described in more detail in section 2.2 below.

2.1.3 PNA

The nucleobases in PNA (peptide nucleic acid, Figure 1) are the same as in DNA and RNA, and their spectral features are thus similar. The chemical shifts of the aromatic protons tend to appear slightly upfield of the corresponding DNA resonances (Figure 3). Each residue of the PNA backbone (\( N\)-(2-aminoethyl)-glycine) contains four pairs of nonexchangeable methylene protons and one exchangeable amide proton. Owing to the different environments of the methylene pairs in PNA, assignments of these can generally be carried out, but stereospecific discrimination cannot be performed unambiguously without specific labeling. Basepairing of a PNA strand to DNA of a complementary sequence results in the formation of a stable hybrid complex that exhibits an NMR spectrum that differs both from the PNA and DNA single strand spectra. A representative spectrum of a PNA strand hybridized to DNA is shown in Figure 3.

2.2 Techniques Used

Nucleic acids of biological significance are often, even as model systems, large enough to pose technical challenges when studied by NMR. Whereas small molecules of DNA are usually tractable solely using their proton resonances, NMR studies of RNA and larger or more complex DNA molecules would be prohibitively difficult without the use of additional paramagnetic nuclei, typically $^{13}$C and $^{15}$N, as labels. Important progress has been made in techniques for producing isotope-labeled DNA and RNA molecules. In addition, partial deuteration of large molecules can be

used to alleviate a number of problems associated with large molecules in NMR experiments.

2.2.1 Isotope Labeling and Sample Preparation

2.2.1.1 RNA Labeling of RNA oligonucleotides with the NMR active isotopes $^{13}$C and $^{15}$N is efficiently done by enzymatic synthesis in vitro. Isotope-enriched nucleotide 5'-triphosphates (NTPs) can be prepared by growing bacterial cells in glucose–mineral salt containing the chosen isotope labels – typically E. coli cells are grown in $^{13}$C glucose and $^{15}$N ammonium sulfate.$^{(7)}$ Alternatively, $^{13}$C methanol may serve as a less costly source of $^{13}$C.$^{(8)}$ After isolation, the nucleic acid chains are degraded to mononucleotides by nuclease treatment. The RNA monomers are separated from DNA and enzymatically phosphorylated to NTPs. The labeled NTPs can then be used as substrate for in vitro transcription using a synthetic DNA template, typically using T7 polymerase, of RNA molecules of the desired length and sequence. Unincorporated nucleotides can be recovered and reused.

The procedure can yield milligram quantities of labeled RNA for NMR experiments. Methods describing base selective isotope enrichment of RNA by residue type and the incorporation of these into large RNA fragments have also been reported.$^{(9)}$

2.2.1.2 DNA A number of strategies have been demonstrated to produce high yields of labeled deoxyribo-nucleotides at low cost.$^{(10)}$ Today there are several strategies that provide uniformly $^{13}$C and $^{15}$N labeled DNA oligonucleotides by enzymatic synthesis.$^{(11–13)}$ Deoxynucleotides can be obtained from bacteria grown on $^{13}$C and $^{15}$N enriched nutrients, isolated and enzymatically phosphorylated to dNTPs. These can be used as building blocks in a polymerase chain reaction (PCR) using a DNA template and a DNA primer carrying a 3'-terminal ribonucleotide. The single 2'OH acts as a substrate for alkaline hydrolysis, which is used to cleave the product strand to be separated from the primer.

Labeled DNA oligomers can be made by cloning multiple copies of the desired oligonucleotide flanked by restriction sites into a plasmid which is transformed into bacteria that are grown with $^{15}$NH$_4$Cl as nitrogen source. The use of $^{13}$C for this purpose is at present excessively costly. Cleavage of the isolated plasmid DNA gives labeled oligonucleotides, with starting material for labeled dNTPs as a side product. Alternatively, endonuclease sensitive repeat amplification, or ESRA, can be performed by running many cycles of PCR to produce very large amounts of DNA fragments that will be $^{13}$C and $^{15}$N labeled if isotope enriched dNTPs are used. Procedures for site specific$^{(14)}$ and region specific incorporation of labeled DNA oligonucleotides$^{(15)}$ have been described as well. These particularly enable highlighting of portions of large DNA molecules or protein–DNA complexes that are of special interest.

2.2.1.3 Partial Deuteration Selective deuteration of oligonucleotides may be introduced in order to suppress part or parts of the proton spectrum. Conditions for efficient deuteration have been worked out for the exchange of pyrimidine H5/H6 and purine H8 protons, and applied to simplify the assignment of homologous DNA repeat sequences.$^{(16)}$ Synthesis protocols for incorporating deuterons stereospecifically in the 2', 3', 4', 5' and 5'' positions in RNA and DNA have been reported.$^{(17,18)}$ Aside from reduced spectral crowding, the advantages of partial deuteration of oligonucleotides include improved resolution and sensitivity. These effects are mainly due to the fact that both the $T_1$ and $T_2$ relaxation times of nuclei vicinal to the deuterons increase considerably.$^{(18,19)}$

It is desirable that NMR samples of macromolecules (such as nucleic acids) are pure. In the case of nucleic
acids it is therefore necessary to include a purification step in the sample preparation in which the desired molecules are separated from fragments of similar size. The most common method for such purification is HPLC (high-performance liquid chromatography) on a reverse-phase column. This is typically followed by exchange of solvent and counter ions on an ion-exchange column or by dialysis.

2.2.2 Experiments

For structure studies of nucleic acids by NMR, the experiments can be divided into three stages. First, one-dimensional spectra are recorded. These are useful for indicating sample purity (both with respect to chemical and conformational composition), sensitivity to pH and temperature, and characteristics such as spectral distribution and the general quality of the spectrum and feasibility of further studies. In addition, the presence of stable basepairs or hydrogen bonds can be seen from one-dimensional spectra. Furthermore, titration with proteins or other ligands is monitored as changes in a one-dimensional spectrum. Second, various multidimensional experiments are recorded in order to establish assignments of as many as possible of the NMR active nuclei in the molecule. Stage three consists of recording quantitative measurements of structural parameters such as internuclear distances (NOE, nuclear Overhauser effect volumes) or dihedral angles (coupling constants) that can be used for structure determination.

In studying nucleic acids in aqueous solution by NMR one has to distinguish between spectra recorded in H₂O and D₂O solution. In H₂O solution all protons are visible (including solvent water), whereas in deuterated solvents only the protons that are covalently connected to the molecule can be detected beside the residual water peak. Because in nucleic acids the labile amino and imino protons generally exchange rapidly and appear mostly downfield of the stable ones, the spectral width of a D₂O experiment can often be kept relatively small, allowing for higher resolution without increasing the amount of data recorded. Disregarding the labile proton resonances, which often require low temperatures (below 10°C) for stabilization and detection, permits spectra in D₂O solution to be recorded at the higher temperatures at which the peak widths tend to be smaller.

There are two particular types of effect that can be measured quantitatively from NMR data – coupling constants and interatom distances. Different varieties of the 2D COSY and NOESY experiments are primarily used for these purposes, respectively. In a COSY spectrum, crosspeaks that show splitting patterns contain information about dihedral angles between protons separated by no more than three bonds. The relation between the coupling constant \( J \), measured as the splitting observed within one crosspeak in a phase-sensitive COSY spectrum, typically measured in Hertz, can be expressed by the semiempirical Karplus equation, Equation (1)

\[
3J = A \cos^2(\phi) + B \cos(\phi) + C
\]

The constants \( A \), \( B \), and \( C \) can be determined from measurements of \( 3J \) in molecules with known values of the angle \( \phi \). Fitting of measured angular data, for example between the protons in a ribose sugar, has been worked out extensively (see Wüthrich(20) and Rinkel and Altona(21)). In a NOESY spectrum of a molecule the size of an oligonucleotide, the crosspeak buildup rate, \( \mu_x \), measured as its integrated volume versus mixing time, is related to the interatom distance of the resonances involved, \( r_{ij} \), as, Equation (2)

\[
r_{ij} = c \mu_x^{1/6}
\]

where \( c \) is a constant that can be determined from a crosspeak representing two covalently connected protons of known separation (e.g. H5–H6 of cytosine or uracil of 2.45 Å, or the intrasugar H2’–H2” distance of 1.85 Å).

Small molecules with a regular conformation, such as double-stranded DNA oligonucleotides or short RNA stems, can often be successfully approached by homonuclear 2D NOESY and COSY experiments, relying on the regular helical conformation for which sequential assignment strategies are relatively straightforward.(12,20)

Sequential assignment of duplex DNA in a B-like conformation(3) is most easily performed in the aromatic–H1’ region of the NOESY spectrum which is characterized by intraredise and sequential crosspeaks of similar intensity. Knowledge of the nucleotide sequence and the expected approximate chemical shifts of the different bases usually suffices to find a trace along the stack of residues. Good markers are the strong intraredise crosspeaks arising from H5–H6 interactions in cytosines, seen in COSY as well as NOESY spectra. Strong intraredise NOESY crosspeaks are also seen from the thymine H6–methyl interactions. These markers are helpful in identifying the H6 of DNA pyrimidines and their 5’ flanking residues. Alternating inter- and intraredise crosspeaks between H6/H8 and H1’ protons (Figure 4) can typically be connected to a trace in the aromatic–H1’ region of a NOESY spectrum. A similar sequential trace can also be followed between the aromatic–H2’ and H2” protons crosspeaks where the intraredise H6/H8–H2” interactions tend to be stronger and resonate slightly downfield compared with the corresponding H2’ protons. Furthermore, the H3’ and H4’ resonances may sometimes be assigned in
the same manner, although weaker sequential interactions and more extensive overlaps often make this more difficult, and additional spectral regions usually need to be analyzed for conclusive assignment of the H3' and H4' protons. Once tentative assignments of the H1', H2 and H2' resonances have been made, these can be crosschecked by identifying the intraresidual cross-peaks in the H1’–H2’ and H1’–H2’ regions of NOESY and COSY spectra. The H2 protons of adenine bases can be distinguished from other aromatic resonances by their characteristically long spin–lattice relaxation times, which can be detected through inversion recovery experiments.\(^{(22)}\)

As for the exchangeable protons, the amino resonances show strong NOEs to the H5 and H6 resonances on the same residue. The thymine imino resonances are most easily identified from their strong interactions with the H2 protons of their respective basepaired adenines. The guanine imino protons show strong NOE interactions with the amino protons of their respective basepaired cytosines. The imino resonances often exhibit sequential imino–imino NOE connectivities among themselves that can be readily traced. However, the imino protons of the terminal basepairs usually exchange too rapidly to be detected under normal experimental conditions.

The assignment of larger molecules that give rise to overcrowded spectra and of molecules of unknown secondary structure, for which sequential assignment strategies break down, requires combination of isotope-labeled samples and various 2D and 3D (three-dimensional) experiments. This need is particularly pronounced for RNA, where overlap in the sugar region is severe and the H1' and H2' coupling is very weak (<3 Hz) in the C3'-endo conformation which generally predominates in RNA sugars. Whereas in a 2D experiment, interactions involving two specific nuclei can be resolved, in a 3D spectrum the involvement of a third nucleus in the magnetization transfer pathway can be visualized. This not only adds resolution along the third dimension, but also offers the possibility of ‘filtering’ the magnetization transfer through a chosen type of nucleus.

When assigning an RNA molecule HMQC (homonuclear multiple quantum correlation spectroscopy) and HSQC (homonuclear single quantum correlation spectroscopy) experiments are useful for classification of nonexchangeable proton resonances through \(^1\)H–\(^13\)C and \(^1\)H–\(^15\)N correlations. Ribose protons can be efficiently assigned by a set of 3D correlation experiments as described by Pardi.\(^{(23)}\) Assignment of all protons in a ribose spin system of a \(^13\)C-labeled sample can be accomplished by performing a set of HCCN–COSY, HCCN–RELAY and HCCN–TOCSY (total correlation spectroscopy) experiments.\(^{(24)}\) The individual ribose spin systems can then be connected by H_6C_5N_6C_3H_8 triple-resonance experiments (s and b refer to sugar and base, respectively) (Figure 5a).\(^{(25,26)}\) A method for sequential through-bond correlation of \(^13\)C-labeled nucleotides has been described,\(^{(27)}\) and through a \(^1\)H, \(^13\)C, \(^31\)P triple-resonance experiment (HCP-CCH-TOCSY) correlation of all ribose protons on both the 5’-side and 3’-side of a backbone phosphate nucleus can be made (Figure 5b). In addition to these experiments, usage of partial deuteration and selectively incorporated isotope labels may increase the resolution and sensitivity as discussed above.

Correlation of the exchangeable amino and imino protons in fully \(^13\)C and \(^15\)N labeled RNA can be done

---

**Figure 4** Schematic illustration of intra- and interresidue dipolar NOE interactions observable in a B-form DNA strand.

**Figure 5** Schematic representation of coherence transfer pathways connecting base and sugar in the HCNCH experiment, indicated in bold gray (a), along the backbone in the HCP-CCH-TOCSY experiment (b), and within the guanine, adenine and uracil bases in the HCNCH-HTOCSY experiment (c).
using HCC(C)NH-TOCSY experiments that are well suited to assigning exchangeable protons in nonregular portions of structures (Figure 5c). To assign DNA structures containing $^{13}$C and $^{15}$N labels strategies that use the same NMR experiments that are used for the assignment of RNA molecules can be applied.

Following successful assignment of the resonances in a molecule, experiments tailored to generate structure information can be conducted. For internuclear measurements, various types of NOESY experiments, such as 3D NOESY/HMOC(32) and four-dimensional HMOC/NOESY/HMOC(7,32) may be used. In addition to homonuclear 2D NOESY spectra, from which interproton distances can be estimated with reasonable accuracy, heteronuclear 3D experiments may be a useful source of distance constraints, particularly for large molecules in which spectral overlap may prohibit the measurement of individual 2D crosspeak intensities.

The use of dihedral angles (derived from J-couplings) in the structure determination of nucleic acids can be of crucial importance, particularly for determining conformations of the backbone where dipolar proton interactions (NOESY crosspeaks) are sparse or difficult to resolve. For unlabeled molecules the determination of sugar conformations from J-coupling data has been described by graphical(21) and simulation(33) methods. For $^{13}$C-labeled nucleic acids, special experiments have been developed to determine a complete set of coupling constants for oligonucleotides.(34) A novel method for quantitative measurements of the three-bond $^{1}H^{3}$−$^{31}P$ couplings in nucleic acids and nucleic acid–protein complexes based on constant time COSY experiments has been reported.(35)

The pioneering technique of measuring dipolar coupling in samples partially oriented by anisotropic cosolutes(36) has been applied to nucleic acids.(37) The cosolute, in this case filamentous phage, becomes aligned in the magnetic field, which is sufficient to extract net through-space $^{1}H$−$^{15}$N dipolar coupling. Double quantum filtered (DQF) COSY experiments carried out with the addition of phage not only have the potential to give a large number of angular constraints that complement distance and J-coupling derived dihedral angle constraints, but also to yield long-range angular information of a type that has not previously been accessible using standard NMR techniques.

Biological molecules in solution always undergo dynamics on different timescales. Perhaps the most well-characterized motion in nucleic acids is the basepair opening dynamics. Imino protons in Watson–Crick basepairs are usually well resolved and thus can, after assignment, report on hydrogen bonding events specific to individual basepairs. The guanine H1 and thymine H3 protons, located in the center of the basepair, are only accessible to exchange after transient opening and lateral motion of one or both of the bases. Amino protons on basepaired cytosines rotate much less frequently than non-base-paired amino protons, resulting in the appearance of well-resolved resonances from hydrogen bonded and exposed protons at characteristic chemical shift intervals (8.0–8.5 ppm and 6.5–7.0 ppm, respectively). Amino protons of adenines and guanines, on the other hand, rotate at intermediate rates and give rise to broad peaks that are often difficult to detect. The exchange of imino protons is catalyzed by base.(38) When paired and open states are in rapid equilibrium the imino protons exchange occasionally and at a measurable rate, $\tau_{ex}$, that depends on the concentration of catalyst [B] and can be expressed according to,(2) Equation (3)

$$\tau_{ex} = \tau_{0} \left(1 + \frac{B_{eq}}{[B]}\right)$$

where $B_{eq}$ is the buffer concentration at which $k_{cl} = k_{tr}$, i.e. the closing rate is equal to the proton transfer rate, and can be estimated from the base concentration for which $\tau_{ex} = 2\tau_{0}$. Extrapolation to infinite buffer concentration gives the basepair lifetime, $\tau_{0}$. The exchange rate is most commonly measured as $\tau_{ex} = (\pi \Delta \nu)^{-1}$, where $\Delta \nu$ is the line width at half height of the resonance of interest. From studies of imino proton exchange it has become clear that the basepair opening rates are sequence dependent. For example, the exchange times of guanine iminos in $G_{n}$ tracts are shorter (less than 5 ms) than in (GC)$_{n}$ tracts or isolated GC basepairs. In contrast the lifetimes of thymine iminos in AT tracts are very long.(39)

Water molecules have an important role in stabilizing nucleic acid structures. This role is partly played by specific association of water molecules to the surface of nucleic acid molecules. Detection of such bound water and estimation of residence times can be done by NMR techniques.(40,41) Interactions between water and nucleic acid protons, for example in one of the grooves of B-form DNA, can be seen as crosspeaks in a NOESY spectrum. Owing to efficient exchange of water molecules between the hydration sites and the bulk, all water peaks appear along the chemical shift of the bulk water signal. It is necessary to differentiate between crosspeaks arising from chemical exchange of water molecules, on the one hand, and exchange NOE crosspeaks arising from nonexchangeable DNA protons and labile DNA protons that exchange rapidly, on the other hand. If the nonexchangeable DNA proton of interest is located close to potentially labile DNA protons, these may appear as slowly exchanging water molecules visible at the chemical shift of bulk water, although they cannot be distinguished from DNA protons in rapid exchange with solvent. DNA protons that exchange rapidly give rise to crosspeaks with the water signal that are positive in a NOESY (NOE
NUCLEAR MAGNETIC RESONANCE AND NUCLEIC ACID STRUCTURES

spectroscopy in the rotating frame) and positive in a ROESY (nuclear Overhauser enhancement spectroscopy in the rotating frame). True water–DNA NOEs, in contrast, will give rise to negative ROESY crosspeaks.

Basepairing through hydrogen bonds primarily manifests itself as imino proton resonances, visible because of the slowed down imino proton exchange. In a reported experiment direct evidence of basepairing hydrogen bonds has been observed. In a $J_{NN}$ COSY experiment of $^{15}$N-labeled RNA two-bond couplings between the N1 of adenosine and the N3 of uracil and between the N1 of guanine and the N3 of cytosine, couplings of approximately 7 Hz have been measured.$^{42}$ Further experimental development has also made possible the observation of $J_{NN}$ coupling between $^{15}$N nuclei with large chemical shift separations, as shown between amino and N7 nuclei in a uniformly $^{15}$N-labeled DNA molecule.$^{43}$

2.2.3 Refinement

Completing a macromolecular structure based on NMR data in practice requires computational modeling into which experimental constraints consisting of internuclear distances and/or dihedral angles can be incorporated. It is generally agreed that the most efficient way of arriving at a molecular structure that satisfies all experimentally derived constraints is to generate a number of starting structures by embedding the molecule according to distance data using so-called distance geometry.$^{44}$ Thereafter, molecular dynamics calculations using one of the available forcefields are carried out, typically using a simulated annealing protocol to account for spin diffusion through non-H1 ribose protons and all intraribose cross-relaxations, respectively. The result of these calculations is a molecular conformation, which can be further refined through network editing techniques, particularly when long NOESY mixing times (>100 ms) are employed.$^{48}$ Experimental methods to overcome this through network editing techniques have been developed. In BDNOESY (band decoupled nuclear Overhauser spectroscopy)$^{49}$ and CBDNOESY (complementary band decoupled nuclear Overhauser spectroscopy)$^{50}$ experiments, pulses are applied during the mixing time that effectively suppress the effects of spin diffusion through non-H1’ ribose protons and all intraribose cross-relaxations, respectively. The resulting data allow tighter error limits during refinement which can be demonstrated on a ribozyme structure.$^{50}$

It has been concluded that RNA molecules as large as 15 kDa do not suffer from being biased by the choice of starting conformation. If the structure relies heavily on interproton distance data and high accuracy, for example regarding sugar pucker conformation, it may be appropriate to include relaxation matrix refinement in the molecular dynamics protocol to account for spin diffusion effects adequately, as discussed below.

Care should be taken to ensure that chirality errors do not occur as a result of refinement processes, which has been observed to happen in numerous reported nucleic acid structures.$^{45}$

2.3 Critical Comments

2.3.1 Accuracy and Validity

Several factors limit how accurately nucleic acid structures can be determined by NMR methods. In solution nucleic acids are not static molecules that adopt structures that can be characterized with infinite accuracy. Rather, RNA and DNA constantly undergo dynamic processes that should be taken into account when describing an RNA or a DNA solution structure. Since NOE intensities do not scale linearly with internuclear distances, it is often not possible to satisfy consistently all NOESY-derived distance constraints and angular constraints within one structure, even if a two-state model with alternate sugar conformations is assumed. However, from analysis of the NOE intensities in a spectrum of a duplex DNA it has been concluded that restricted rotational diffusion around the glycosidic bond, $\chi$, combined with sugar repuckering can explain the observed spectral features satisfactorily.$^{46}$ Furthermore, from relaxation studies of $^{13}$C-labeled purines in a duplex it has been found that in addition to overall isotropic tumbling, which occurs on the timescale of 3–4 ns, there is fast (20 ± 20 ps) internal motion of individual purines. This motion, if described as wobble-in-a-cone, is restricted to ±22.5° for the 1’, 3’, 4’, 2 and 8 protons in the purine, with no apparent sequence dependence.$^{47}$

2.3.2 Potential and Limitations

The effects of spin diffusion give rise to significant errors in NOE-derived internuclear distance measurements, particularly when long NOESY mixing times (>100 ms) are employed.$^{48}$ Experimental methods to overcome this through network editing techniques have been developed. In BDNOESY (band decoupled nuclear Overhauser spectroscopy)$^{49}$ and CBDNOESY (complementary band decoupled nuclear Overhauser spectroscopy)$^{50}$ experiments, pulses are applied during the mixing time that effectively suppress the effects of spin diffusion through non-H1’ ribose protons and all intraribose cross-relaxations, respectively. The resulting data allow tighter error limits during refinement which can be demonstrated on a ribozyme structure.$^{50}$

It has been concluded that RNA molecules as large as 15 kDa should be amenable to structure determination by NMR methods with a precision and accuracy of 1–1.5 Å.$^{51}$ It is also noted that the most substantial improvements in structure quality were accomplished by including constraints derived from exchangeable protons rather than using narrower distance constraints. The molecular size limit is to a large degree set by the availability of experimental constraints – internuclear distances and dihedral angles. The number of constraints per residue is more likely to be large in molecules with
globular shapes, such as compactly folded RNAs. Thus, with instruments of higher sensitivity and with efficient labeling techniques and more robust refinement methods the future appears promising for structure studies of molecules of increasing size.

3 STRUCTURES DETERMINED

3.1 DNA Motifs

3.1.1 Duplex Structures

Among the many solution structures of DNA oligomers that have been determined by NMR methods, the structure of the TATA-box containing self-complementary octamer d(GGTATACC) will be discussed first.\(^{(48)}\) The final structures of the octamer duplex were based solely on interproton distance constraints, with the effects of spin diffusion accounted for by inclusion of relaxation matrix calculations in the refinement protocol. The use of a 3D proton NOESY–NOESY experiment (120 ms mixing time in both indirect dimensions) clearly illustrated spin-diffusion pathways as crosspeaks appearing at chemical shifts that were different in all three dimensions. For example intraresidue H6 → H2′ → H3′ and H6 → H2'' → H1' crosspeaks were seen, demonstrating that the H2' and H2'' protons mediate spin diffusion efficiently. Similar diffusion pathways were also seen in sequential aromatic–sugar interactions. From the resulting structures it was concluded that the molecule in solution adopts a structure that relatively closely approximates the canonical B-conformation.

DNA displays structural irregularities – sequence and condition-dependent features that may be crucial to its biological function. A molecular structure of extended shape, such as a DNA duplex, determined from short-range distance constraints, has an intrinsic lack of accuracy attached to it. It should thus be pointed out here that the structural details that may be sought in a high-resolution structure of an oligonucleotide duplex alone in solution need to be most carefully established in order to merit significant conclusions to be based upon them.

3.1.2 Triplex Structures

DNA of appropriate sequences under favorable conditions will form three-stranded complexes. A number of different triplet basepairing schemes have been observed, as reviewed by Radhakrishnan and Patel.\(^{(52)}\) The most commonly encountered triplex is based on the pyrimidine-purine–pyrimidine motif. In this complex, the Watson–Crick pairing pyrimidine-rich strand runs antiparallel to the purine-rich strand to which the second pyrimidine strand binds in a parallel alignment through Hoogsteen hydrogen bonds (Figure 6).

The hydrogen bonds predicted for this motif were confirmed by NMR studies focusing on exchangeable resonances and strand orientation.\(^{(53,54)}\) Stable formation of such triplexes requires protonation of the cytosines on the Hoogsteen strand, and is thus favored by low pH. The one-dimensional proton NMR spectrum of a unimolecular DNA triplex that includes a G·T·A triplet in the center is shown in Figure 7.

A few notable features will be pointed out. First, the cytosine imino protons appear downfield of the other imino proton peaks (14.5–16.0 ppm). Downfield shifting of the exchangeable as well as nonexchangeable protons in the protonated cytosine generally follows upon protonation. Second, the thymine iminos
on the Hoogsteen strand resonate somewhat upfield (12.8–13.9 ppm) of the Watson–Crick thymine imino resonances (13.8–14.6 ppm). Third, both of the adenine amino protons are engaged in hydrogen bonding and appear in the 8.0–8.5 ppm region, whereas the hydrogen-bonded amino resonances of the protonated cytosine appear between 8.5 and 10.0 ppm. The spectrum of exchangeable protons is thus mostly well resolved, the imino resonances of the thymine loops seen around 11 ppm being an exception. The imino and amino protons in the Watson and Crick strands in this sequence were assigned by strategies similar to those described for a regular duplex (section 2.2 above) using 2D NOESY spectra recorded in H₂O solution with intermediate mixing times (120 ms). In addition NOESY crosspeaks between thymine imino protons in T-A-T triplets and hydrogen bonded adenine amino protons are observed. The Hoogsteen pairing imino protons in the T-A-T triplets show NOEs to the H8 of the adenine and to the hydrogen-bonded adenine amino proton. The H8 of all adenines and guanines can be selectively deuterated in order to aid the identification of some of the imino crosspeaks. For the C⁺-G-C triplet, strong NOEs are seen between the hydrogen-bonded and exposed amino protons on the protonated cytosine Hoogsteen-bound to the guanine.

The nonexchangeable protons of the molecule were assigned from a 3D NOESY/TOCSY experiment. In this experiment the first step is a dipolar interaction NOE, whereas the second step involves a coherent transfer of magnetization between scalar coupled spin pairs. The experiment facilitated identification, for example of the various protons showing NOE interactions with H2⁺ and H2⁻⁺ protons, which in turn exhibit strong couplings with the well-resolved H1⁺ resonances. The 3D structure of the triplex (sequence in Figure 7) is shown in Figure 8. The triplex was allowed to form in solution with Li⁺ as counterions to avoid formation of four-stranded complexes which may be favored in G-rich sequences with Na⁺ or K⁺ present. The Watson–Crick paired strands do not deviate substantially from a regular duplex conformation, although some basepair displacement and helical unwinding is seen. The glycosidic angles are all in the anti domain and all sugars are in the S conformation, except for the guanine of the G-T-A triplet, which adopts the N

**Figure 8** Stereo view of DNA triplex containing a G-T-A triplet, loops excluded. Strand I corresponds to bases C1–C7, strand II to G8–G14 and strand III to C15–C21 in the sequence shown in Figure 7. The strands are labeled at their 5' ends. (Reproduced by permission of Dr. D.J. Patel of Sloan-Kettering Institute, New York.)
conformation. While the base triples are generally planar, the guanine of the G-T-A is tilted towards the 3’ direction. The grooves are all different, with the Watson–Crick groove being slightly narrower than in a duplex with a fairly smooth surface. The Watson–Hoogsteen groove in contrast appears largely wide, shallow and uneven. The Crick–Hoogsteen groove is narrow and has distinct cavities on its surface. Considering its lining of polar residues, this groove provides potential binding sites for water or positively charged ions. Ordered water molecules in the Crick–Hoogsteen groove have indeed been found, as shown from a combination of homonuclear NOESY and ROESY experiments carried out on the same triplex molecule.\(^{57}\)

Similarly, in the Watson–Hoogsteen groove, water molecules with residence times longer than 1 ns were found. The water molecules in the Watson–Crick groove of this triplex were found to be more mobile, in contrast to the spine of hydration found in the minor groove of duplex DNA.\(^{41}\)

### 3.1.3 Quadruplex Structures

Four-stranded DNA complexes have received much attention, partly owing to their potential relevance to telomere sequences (guanine-rich multiply repeated short sequences at the ends of chromosomes). Understanding the structure and topology of these repeat sequences may lead to functional insights of biological or medical importance. Several types of intra- and intermolecular quadruplexes with different types of pairing alignments and combinations of strand directionalities have been studied (reviewed by Rhodes and Giraldo\(^{58}\) and Darlow and Leach\(^ {59}\)). Both NMR and X-ray crystallography methods have been employed to determine structures of DNA quadruplexes.

Generally, G quartets (Figure 9) are highly stable, as has been evidenced, for example, by NMR studies of the human telomere sequence. Upon change of solvent from H\(_2\)O to D\(_2\)O the exchange of the imino protons with deuterons occurred at remarkably low rates that could be followed over days in the NMR spectrum.\(^{60}\)

Quadruplexes generally require the presence of low concentrations of monovalent cations for their stability, often discriminating between different types of ions. Typically potassium and sodium ions are found to coordinate the arrangement of bases in and between the tetrads, whereas lithium ions are too small to fulfill this function.

As an example of a four-stranded complex the structure formed by GGGC repeats, found in adeno-associated viral DNA, will be discussed.\(^{61}\) In addition to forming G-tetrads this structure also forms G-C-G-C quartets (Figure 10). The four strands, combined by head-to-tail dimerization of two hairpins, run antiparallel to each other around the quadruplex, with lateral T\(_4\) loops connecting the pair of arms on each hairpin. The interaction between the two intrastrand Watson–Crick GC basepairs is mediated by bifurcated Hoogsteen hydrogen bonds involving the major groove edges of the bases. In guanine tetrads the *syn* conformation around the glycosidic bond is commonly observed. In the present example the guanines of the G2 and G10 in the G-C-G-C tetrads are in the *syn* form, while the remainder of the bases are in the *anti* conformation.

The spectrum of this sequence (Figure 11a) in H\(_2\)O solution containing sodium ions shows two resonances between 13.0 and 13.4 ppm, characteristic of Watson–Crick interactions, and four additional peaks between 11.1 and 12.0 ppm, characteristic of G\(_4\) tetrad formation.\(^{62}\) The number of peaks seen in the spectrum shows that any four stranded complex formed must possess two-fold symmetry. All four cytosine amino protons of one symmetric unit are seen in the 8.7–9.4 ppm region, indicating that they all are engaged in hydrogen bonding.

Unambiguous assignment of the guanine imino proton resonances was reached through site-specific

**Figure 10** Topology of quadruplex structure formed by d(G\(_1\)G\(_2\)G\(_3\)C\(_4\)T\(_5\)T\(_6\)T\(_7\)T\(_8\)G\(_9\)G\(_10\)G\(_11\)C\(_12\)).

---

\(^{57}\) Similar to the Watson–Crick groove, water molecules with residence times longer than 1 ns were found. The water molecules in the Watson–Crick groove of this triplex were found to be more mobile, in contrast to the spine of hydration found in the minor groove of duplex DNA.

\(^{41}\) Similarly, in the Watson–Crick groove, water molecules with residence times longer than 1 ns were found. The water molecules in the Watson–Crick groove of this triplex were found to be more mobile, in contrast to the spine of hydration found in the minor groove of duplex DNA.

\(^{58}\) For the structure and topology of these repeat sequences may lead to functional insights of biological or medical importance. Several types of intra- and intermolecular quadruplexes with different types of pairing alignments and combinations of strand directionalities have been studied (reviewed by Rhodes and Giraldo\(^ {58}\) and Darlow and Leach\(^ {59}\)). Both NMR and X-ray crystallography methods have been employed to determine structures of DNA quadruplexes.

\(^{59}\) As an example of a four-stranded complex the structure formed by GGGC repeats, found in adeno-associated viral DNA, will be discussed.\(^ {61}\) In addition to forming G-tetrads this structure also forms G-C-G-C quartets (Figure 10). The four strands, combined by head-to-tail dimerization of two hairpins, run antiparallel to each other around the quadruplex, with lateral T\(_4\) loops connecting the pair of arms on each hairpin. The interaction between the two intrastrand Watson–Crick GC basepairs is mediated by bifurcated Hoogsteen hydrogen bonds involving the major groove edges of the bases. In guanine tetrads the *syn* conformation around the glycosidic bond is commonly observed. In the present example the guanines of the G2 and G10 in the G-C-G-C tetrads are in the *syn* form, while the remainder of the bases are in the *anti* conformation.

\(^{60}\) The spectrum of this sequence (Figure 11a) in H\(_2\)O solution containing sodium ions shows two resonances between 13.0 and 13.4 ppm, characteristic of Watson–Crick interactions, and four additional peaks between 11.1 and 12.0 ppm, characteristic of G\(_4\) tetrad formation.\(^ {62}\) The number of peaks seen in the spectrum shows that any four stranded complex formed must possess two-fold symmetry. All four cytosine amino protons of one symmetric unit are seen in the 8.7–9.4 ppm region, indicating that they all are engaged in hydrogen bonding.

\(^{61}\) Unambiguous assignment of the guanine imino proton resonances was reached through site-specific
incorporation of $^{15}$N isotopes in the N1, N2 and N7 positions of bases G1 and G10. Differences in the proton spectral pattern between $^{15}$N decoupled and $^{15}$N undecoupled spectra then enabled identification of the G1 and G10 imino proton resonances, which in turn permitted the assignment of the remaining imino protons of the molecule through analysis of NOESY spectra. The involvement of the G1 and G9 imino protons in G-C Watson–Crick base pairing was concluded from their showing NOEs to cytosine amino and H5 protons on the opposing base. Each of the G2, G3, G10 and G11 imino protons exhibits an NOE to the guanine H8 proton in the Hoogsteen aligned position. In the nonexchangeable proton NOESY spectrum strong intraresidue crosspeaks between H1' and H8 are seen for G2 and G10 at short mixing times, evidence of a syn conformation around the glycosidic bond. The 3D structure of d(GGGC-TTTT-GGGC) stabilized by 100 mM Na$^+$ is shown in Figure 12(a). The quadruplex has four grooves, of which two are equivalent and wide-formed within each hairpin.

![Figure 11 Proton spectra of d(G1G2G3C4T5T6T7T8G9G10-G11C12) in H2O solution at 10 °C stabilized by 100-mM Na$^+$ (a), and 100-mM K$^+$ (b). (Reproduced by permission of Bouaziz et al., J. Mol. Biol., (1998) Academic Press.)](image)

The other two grooves are nonequivalent and narrow and are formed by the G1-G2-G3-C4 and G9-G10-G11-C12 interstrand interactions.

![Figure 12 Structure of quadruplex formed by d(G1G2G3C4T5-T6T7T8G9G10G11C1) stabilized by 100-mM Na$^+$ (a), and by 100-mM K$^+$ (b). (Reproduced by permission of Bouaziz et al., J. Mol. Biol., (1998). Academic Press.)](image)
An interesting isomerization occurs in the molecule upon shifting from Na⁺ to K⁺ as the predominant counterion in the sample solution. The change is manifested as distinctly different features in the proton NMR spectrum (Figure 11b). The spectrum of exchangeable protons shows that the molecule remains in a structure of two-fold symmetry, but that the basepairing pattern is different with K⁺ ions present. The cytosine amino protons no longer appear close together, instead two of them have shifted upfield, indicating that they are no longer hydrogen bonded. The NOESY crosspeaks indicative of G·C·G·C tetrads (i.e. between H8(G1) and H5(C4) and between H8(G9) and H5(G12)) are not observed in the K⁺ form of the quadruplex. A basepairing scheme for the G·C·G·C planes of the quadruplex with intrastrand Watson–Crick hydrogen bonds, but without pairing interactions in between the two strands was concluded. The K⁺ stabilized structure remains a quadruplex (Figure 12b), but one with different hydrogen bond patterns in the outer tetrads and with T4-loop structures that differ from the ones seen in Na⁺ solution (Figure 13).

A novel method of directly localizing the cation binding sites in DNA quadruplexes has been reported. The $^{15}$NH$_4^+$ ion was used as a probe of cation coordination of G-tetrads, replacing Na⁺ or K⁺. In $^{15}$N filtered proton spectra of the *Oxytricha nova* telomere sequence d(G1T2G3C4T5T6T7T8G9T10), the ammonium ions showed three distinct peaks at low pH. These could be assigned to NH$_4^+$ ions bound to two different DNA sites, populated as 2:1, while one much larger peak arises from bulk NH$_4^+$ ions. From ROESY and NOESY experiments the ammonium ions could be mapped to loci between the planes of the G-tetrads (cf. section 2.2). Two more ammonium ions, one on either end of the quadruplex, are bound between the central G4 tetrads and its flanking outer tetrad. From measurements of the resonance line widths of the coordinated NH$_4^+$, their lifetimes were estimated to over 50 ms for the outer ions [N.V. Hud, P. Schultze, V. Sklenář, J. Feigon, ‘Binding Sites and Dynamics of Ammonium Ions in a Telomere Repeat DNA Quadruplex’, *J. Mol. Biol.*, **285**, 233–243 (1999)]. From chemical exchange N$_2$-Ex-HSQZ experiments with varying mixing times it was estimated that ammonium ions binding to the inner sites have residue times as long as 250 ms. These experiments also gave evidence for a pathway along which the NH$_4^+$ ions enter the quadruplex through the end openings of the cavity running along the helix axis and not through the grooves.

### 3.1.4 DNA–Drug Complexes

DNA interacting with small molecules will here be represented by the binding of the chiral transition metal complex [Ru(phen)$_3$]$_{2}^{2+}$ and the oligonucleotide [d(CGCGATCGCG)]$_{2}$. The propeller shaped Ru-complex binds to the oligonucleotide with some sequence preference and with exchange kinetics that are rapid on the NMR timescale (milliseconds). While the fast kinetics precludes determination of a well-defined DNA–metal complex structure by NMR methods, conclusions about the type of interaction and its effects on the structure of the DNA oligomer can be reached.

Figure 14 shows the change in the aromatic region of the one-dimensional proton spectrum as the Ru/oligonucleotide duplex concentration ratio increases. Most notably a few resonances, both of the oligonucleotide and of the phenanthroline ligands, shift drastically as more Ru-complex is added. These chemical shift changes can be used to estimate binding constants for the metal complex, which were found to be in the range of $10^3$–$10^4$, and also to provide evidence for sequence and groove specific interactions. In the sequence studied the most marked effects are seen around the central AT step where the chemical shift of the H2 proton of adenine reports drastic alterations in its local environment. Crosspeaks in NOESY spectra of the [Ru(phen)$_3$]$_{2}^{2+}$–oligonucleotide complex supplied strong evidence for binding in the AT region of the minor groove – many intermolecular NOEs of varying intensities were observed. The NOESY data also indicates that the DNA molecule does not undergo any significant structure changes but remains in a B-like conformation, and that the metal complex binds in a nonintercalative fashion.
3.1.5 DNA–Protein Complexes

The structure of the lymphoid enhancer-binding factor (LEF-1) to a 15 basepair long DNA oligomer will serve here to exemplify DNA–protein complex structures. The high-mobility group (HMG) of LEF-1, containing 84 amino acids, was bound to the oligonucleotide 5'-CACCCCTTGAAGCTCGCTGACGCTAATT-3' (bold face representing the protein binding site) in a 1:1 stoichiometric ratio, and the structure was determined by NMR methods. Unacceptably 13C,15N labeled LEF-1 and an extensive array of 2D and 3D experiments were used. The DNA portion of the complex was assigned from 2D 13C,15N double half-filtered NOESY and 13C half-filtered NOESY and 13C-decoupled homonuclear proton NOESY spectra. NOE crosspeaks between LEF-1 and DNA were identified from a 3D 13C-edited 12C-selected NOESY experiment. The structure determination was based on nearly 1450 intraprotein, 325 intra-DNA and 332 intermolecular distance constraints, and 42 dihedral angle constraints for the protein. The HMG domain of LEF-1 is dominated by three α-helices arranged to give it an L-like shape. The protein is wrapped around the DNA, forcing it to bend into a compressed major groove. Intimate protein–DNA contacts are formed between a concave surface of LEF-1 and the minor groove of the oligonucleotide where a methionine side chain is partly intercalated, wedging into the DNA without disrupting any of its basepairs.

3.2 RNA

3.2.1 Choice of Domains

Many RNA molecules of interest are prohibitively large for structure determination using NMR methods. This problem can often be circumvented by reducing the size of the RNA molecule of interest to a minimum portion that retains its specific functions. In some cases the anticipated secondary structure of an RNA molecule can suggest how such reductions may be performed without excluding vital interactions. A few structure motifs have been observed to reoccur in several RNA structures. The UUGC and GNRA tetraloops (where N signifies any base and R signifies a purine) are examples of this. The stable GNRA loop has also been used to cap a shortened stem or to connect loose ends, for example in the U1A binding RNA polyadenylation inhibition element. The stability of the GNRA loop has been found to form a network of heterogeneous hydrogen bonds and extensive base stacking within the loop, explaining its unusual stability. It should also be kept in mind that an RNA molecule that specifically binds to a ligand may not be correctly folded, or may not even adopt a stable structure, in the absence of its cognate molecule. An example of this is given by the AMP (adenosine monophosphate) aptamer RNA. Furthermore, magnesium ions often play important roles in RNA structure stability.

3.2.2 Examples of RNA Structures

3.2.2.1 Adenosine Monophosphate–RNA Aptamer

An RNA aptamer structure can be nicely illustrated by an ATP (adenosine triphosphate) specific sequence of which...
the structure has been determined by NMR methods. In vitro selection performed on a column to which ATP was attached via a linker to its C8 position, combined with enrichment procedures, yielded a consensus sequence from a pool of RNAs 169 nucleotides long.\(^\text{[70]}\) This sequence could be shortened to a 40-mer containing an 11 nucleotide consensus sequence (Figure 15) keeping its ATP affinity, which was characterized by a \(K_d\) (dissociation constant) of about 10 \(\mu\)M. The affinity was found to be the same for adenine and AMP as for ATP, and to increase upon raising the concentration of Mg\(^{2+}\).

The aptamer molecule was, based on its sequence, proposed to adopt a structure containing an internal loop opposite an invariant guanine, flanked by two basepaired stems. This prediction was confirmed by two independent structure studies. The 40-mer RNA aptamer, shown in Figure 15, in a complex with AMP was determined by Jiang et al.,\(^\text{[71,72]}\) and Dieckmann et al.\(^\text{[73]}\) have determined a closely related 36-mer RNA–AMP.

Structure determination by NMR methods revealed that the conserved internal loop and the bulged guanine fold around the ATP in a compact manner, embracing most of the purine portion of the AMP, leaving only its C8 edge exposed (Figure 16). The backbone of this portion of the RNA has been likened to a Greek zeta (ζ). The loop nucleotides G8, A9 and A10 combine with the AMP to stack in a way similar to a GNRA turn.\(^\text{[68]}\) Two asymmetric G-G mismatch basepairs, one of them involving the bulged G34, cap the two helical stems that extend from the loop, giving the entire aptamer an L-like shape. Based on nearly 40 intermolecular NOEs between the AMP and several of the bases in the loop, the AMP could be located quite precisely. The AMP was found to stack between the A10 and G11 bases of the RNA loop. The RNA molecule was found to undergo an AMP-induced structural transition,\(^\text{[69]}\) evidenced by the appearance of 10 new resonances from exchangeable protons upon addition of AMP.

Assignment of the AMP aptamer complex presented challenges, not only because of the size of the system, but also because of the unknown structure of the internal loop which, in combination with the large number of NOEs observed, makes it difficult to distinguish sequential from long-range interactions. For the unambiguous assignment of the AMP aptamer, a variety of multidimensional experiments were carried out on samples of unlabeled and uniformly \(^{13}\)C and \(^{15}\)N labeled RNA and AMP. The use of labeled RNA in a complex with unlabeled AMP, or vice versa, permitted the distinction of intra- from intermolecular NOE interactions involving the RNA and AMP molecules.\(^\text{[72,74]}\)

Identification of exchangeable proton resonances in the internal loop can be approached by different strategies.\(^\text{[74,75]}\) Site-specific \(^{15}\)N labeling of RNA purines (N1 imino and N2 amino positions in guanines and N6 amino positions in adenines) of most purines one at a time in the loop and bulge regions of the AMP–RNA aptamer made possible the assignment of the exchangeable protons in this region. The specifically isotope-labeled bases required for this strategy may, however, not be readily available. In an alternative approach, the guanines of the internal loop and the bulge guanine were systematically substituted for inosine. The replacement by inosines causes a downfield shift of nearly 2 ppm of the corresponding imino proton, facilitating its assignment. However, some of the inosine-for-guanine substitutions resulted in weakened binding of AMP, suggesting cautious use of
the inosine substitution strategy.\textsuperscript{(75)} One assignment of special importance for this structure is the proton of the 2'-hydroxy group of G34, which shows a large number of NOEs to surrounding RNA and AMP protons. This hydroxy proton was identified from its appearance as a singlet peak in spectra of uniformly \textsuperscript{13}C and \textsuperscript{15}N labeled RNA recorded without decoupling, thus excluding it from being attached to a carbon or a nitrogen atom. It is notable that the OH-proton appeared extensively downfield shifted (9.34 ppm) compared with previously observed hydroxy proton resonances (ca. 6.8 ppm in the UUGC loop\textsuperscript{(76)}).

The exchange rates of RNA imino protons have been measured in the AMP–RNA aptamer complex.\textsuperscript{(77)} The study reported that the imino protons around the ATP-binding loop containing several non-Watson–Crick basepairing interactions are stabilized by ATP complexation, as well as those in its surrounding stem basepairs. Furthermore, the exchange time of the sugar 2'-OH proton of G34 (Figure 15) was measured successfully and found to be about 20s, which is very long compared to the corresponding 2'-OH in a ribonucleoside monomer (\textless{}1 ms), lending strong support to this hydroxy group participating in hydrogen-bond formation.

### 3.2.2.2 RNA–U1A Protein

As a representative structure of RNA–protein complexes determined by NMR, the human U1A protein bound to an RNA molecule containing the polyadenylation regulatory element of the pre-mRNA 3'-UTR (untranslated region) will be discussed. The 30 nucleotide long RNA sequence, shown in Figure 17, contains a flexible internal loop, which becomes ordered when binding to the protein. The RNA binding domain of U1A comprises residues 2–102, and contain the amino terminal ribonucleoprotein domain. For reasons of sample stability the U1A protein studied contained two mutations of amino acids not directly involved in RNA recognition, which gave a \(K_d\) of less than 10\textsuperscript{-9} M with the RNA construct. The strategy chosen for assigning the RNA–protein complex was to make extensive use of previously obtained assignments of the free components.\textsuperscript{(78)} This was found attractive partly because of the higher spectral quality of the individual components compared with the complex. The RNA component had been previously assigned both alone and in complex with U1A.\textsuperscript{(67)} Resonances originating from the protein and the RNA resonances and their respective NOE crosspeak patterns were distinguished in spectra of the complex, based on their chemical shift differences – RNA only rarely gives rise to signals upfield of 3.5 ppm – and from spectra of complexes containing double-labeled protein. The helical portions of the protein were mostly unaffected by RNA binding, except for one of the helices for which large chemical shift changes occur. Only a minority of the amino acid residues could not be assigned from comparison with free protein. For these residues heteronuclear through-bond correlation data obtained with \textsuperscript{13}C/\textsuperscript{15}N double-labeled protein was used.

Intermolecular interactions were observed selectively through 2D half-filtered experiments on isotope-labeled protein in complex with unlabeled RNA.\textsuperscript{(79)} Most intermolecular NOEs were identified from 3D \textsuperscript{13}C-edited spectra of labeled protein in complex with unlabeled RNA. In total more than 2600 unambiguous distance constraints were used for structure refinement. A majority of these, over 1700 constraints, came from intramolecular protein interactions, near 600 from the RNA internally and 123 constraints were intermolecular. In addition, more than one hundred dihedral angles and 25 hydrogen bonds were used to determine the RNA component.\textsuperscript{(78)} The resulting structure, Figure 18, shows that the RNA molecule is severely kinked and that its helical parts interact with the variable loops of the protein. The \(\beta_2–\beta_3\) loop

![Figure 17](image1.png) Sequence of U1A binding RNA.

![Figure 18](image2.png) Structure of the RNA binding domain of human U1A bound to the RNA binding portion of the polyadenylation regulatory element of the U1A pre-mRNA 3' UTR studied by Allain et al.\textsuperscript{(5)} Protein shown in space filling (cyan), and RNA shown in stick representation. RNA residues interacting with the protein are shown in orange and magenta.
protrudes through a hole in the RNA formed between the internal loop and the helical stems. The single stranded residues of the RNA internal loop are splayed out across the surface of the β-sheet of U1A, with each of the nucleotides engaged in intra- or intermolecular stacking or hydrophobic interactions with other bases or aromatic protein side chains.

3.3 PNA and Other Variations

A growing interest in employing the basepairing specificity of nucleic acids to target specific genes has spurred the development of nucleic acid analogs tailored to combine improved function with desired properties (reviewed by Mesmaeker et al.).(80) Several modifications of the DNA backbone have been implemented in this pursuit, including substitutions within the phosphate groups and modification of the sugar moieties, as well as replacement of the entire sugar phosphate skeleton by a peptide-like chain, as in PNA (Figure 1). Insights into the structure of these DNA analogs may lead to an understanding of their function, as well as suggesting ways of modifying them for improved applicability. PNA forms stable hybrid duplexes with both DNA and RNA, and forms PNA-DNA–PNA triplexes with purine-rich DNA strands.(81)

3.3.1 PNA–DNA Hybrid Duplex

The structure of the PNA–DNA hybrid H-GCTATGTC-NH$_2$-d(GACATAGC) has been studied. (6) Generally assignment strategies of PNA protons need to be tailored to the specific system. In the instance of a PNA–DNA duplex the assignment of the PNA strand was complicated because of the lack of an easily observed continuous sequential crosspeak pattern along the exchangeable portion of the PNA protons. Instead, aromatic–methyl crosspeaks within thymines and their flanking residues were used to identify sets of three residues, which, along with similar patterns around H5−H6 interactions in cytosines, allowed assignment of all aromatic protons. The imino resonances, assigned via the DNA strand were, together with the adenine H2 crosspeaks, useful for confirming these assignments and for assigning additional exchangeable basepairing protons. The amide resonances were assigned from their NOEs to the H6/H8 protons on their own and N-terminal side flanking residues. The amide–aromatic NOEs observed in H$_2$O solution provide a pattern that may be amenable to sequential assignment. Scalar interactions, seen as TOCSY crosspeaks, were seen between backbone amide protons and the intraresidue H4 and H5 protons of the preceding residue. Each aromatic H6/H8 proton on the PNA strand shows several NOEs to the C7, C4' and C5' methylene protons, which confirm the assignments of these protons. The pattern in the aromatic–sugar region of a NOESY spectrum shows typical B-form characteristics such as anti glycosidic bonds and near C2'-endo sugar conformations for the DNA strand. (82) Determination of the 3D structure of the hybrid duplex revealed a B-like conformation with a wide major groove and a narrower minor groove. (6) Somewhat irregular basepair stacking was observed and was supported by an unusually dispersed imino proton spectral region and by several interstrand NOE interactions. The structure of this PNA–DNA duplex is in many ways similar to the Watson–Crick portion of a PNA-DNA–PNA triplex structure that was determined by X-ray crystallography methods. (83)

3.3.2 PNA–RNA Hybrid Duplex

A PNA strand basepaired to an RNA oligonucleotide adopts a different conformation and requires different assignment strategies. Assignment of a PNA–RNA duplex was accomplished by incorporating a single fully $^{15}$C–$^{15}$N labeled thymine residue in the PNA strand, which was helpful in several ways. First, it helped to identify the labeled residue in double quantum or TOCSY spectra. Second, through NOESY experiments its neighboring residues could be identified. Third, 2D $^{13}$C filtered NOESY experiments were useful for characterizing the local backbone conformation. Sequential NOE connectivities were observed throughout the PNA strand. The structure of a PNA–RNA hexamer duplex was determined and found to be in an A-like conformation with C3' endo sugars in the RNA strand. The PNA strand backbone has many features in common with the one of the PNA–DNA hybrid.(81)

4 FUTURE OUTLOOK

New developments are under way that will move the horizon of the impossible further away. Most of the newly developed techniques work more efficiently at higher magnetic fields, and hence may be increasingly used as NMR instrumentation becomes further advanced.

4.1 Transverse Relaxation

Transverse relaxation optimized spectroscopy (TROSY) is a new technique used to measure scalar couplings in large molecules. TROSY experiments have been used to measure $^{15}$N–$^{15}$N and $^{15}$N–$^1$H couplings through hydrogen bonds in DNA and should be applicable to large molecules such as nucleic acids in complexes with proteins.(85)
4.2 Oriented Samples

Newly developed NMR methods that use the addition of matrixes to the sample in order to accomplish a net orientation of the sample, have proven powerful for protein structure determination.\(^{(36)}\) By measuring the orientation of vectors in the molecule (derived from different coupling constants measured at different magnetic field strengths), the orientation of molecular vectors such as amide and carbonyl bonds can be determined independently relative to the magnetic susceptibility tensor of the molecule. The magnetic susceptibility is relatively large in aromatic molecules, particularly when ordered in a stacked manner. Thus nucleic acid molecules give efficient contributions to the measurability of dipolar couplings. The dipolar effects increase as the square of the magnetic field strength and can therefore be expected to become a more studied phenomenon as higher field NMR instruments become available. Dipolar couplings were measured and used to determine the structure of the DNA binding domain of the transcription factor GATA-1 bound to an oligonucleotide.\(^{(36)}\) In a different study the addition of a filamentous bacteriophage was used to increase the degree of anisotropy in the sample and it was shown that in addition to heteronuclear dipolar couplings, \(^{1}H–^{1}H\) dipolar couplings could also be measured.\(^{(37)}\) These recent developments may present a novel approach to one of the holy grails of DNA structures – the overall shape and the extent of any sequence-dependent bend of a molecule – which traditional methods that rely on short-distance constraints that easily accumulate small errors have failed to answer.

ACKNOWLEDGMENTS

I am grateful to Dr. Asif Suri and Mr. Tommi Ratilainen for their assistance in figure preparation, and to Dr. Bengt Nordén for valuable comments on the manuscript.

NUCLEAR MAGNETIC RESONANCE AND NUCLEIC ACID STRUCTURES

44. A.T. Brünger, X-plor Manual V. 3.1, The Howard Hughes Medical Institute and Department of Molecular Biophysics and Biochemistry, Yale University, 1992.

The general relations between structure and energetics of nucleic acids are described. A detailed, multileveled definition of the structures adopted by one, two, three and four strands is presented, with emphasis on the chemical functionalities of the structural subcomponents. Descriptions include results from studies of the thermodynamics of transformations and structures (e.g. double helix formation, superhelical coiling). Different aspects of this large array of problems have been determined using X-ray diffraction and spectroscopic techniques, such as ultraviolet (UV) and infrared (IR) absorption, circular dichroism (CD), Raman scattering and nuclear magnetic resonance (NMR). Interactions, within one strand or between two or more strands, with cations, buffers, aromatic chemicals and proteins are all described. Methods include spectroscopy, calorimetry and computational approaches (statistical mechanics, molecular mechanics, dynamics, quantum mechanics). A Further Reading section is included to provide an idea of the vast scope of this area.

1 INTRODUCTION

The foundation of life itself is encoded by a vast array of nucleic acids. The functional capability of a particular nucleic acid in its biological niche is determined by the viability of its physical structure. As with all chemical species, the assumed structure is a compromise between stabilizing and repulsive interactions between and among the functional subcomponents. The relations between structure, function and energetics are complicated, and therefore require a detailed, multileveled definition. The structures of nucleic acids are so varied and numerous that we can only summarize a broad selection of the key areas. A much less inclusive selection of the associated energetics is discussed, only providing an overview of general approaches. The cited literature expands upon the methodology, assumptions and interpretations, presenting a reasonably broad, but by no means exhaustive, perspective of the subject.

2 ORGANIZATION OF STRUCTURAL HIERARCHY

Nucleic acid structure are classified in a hierarchical manner, beginning with the simplest components and proceeding to progressively larger assemblies. Associations between two or more simple subcomponents produce secondary and tertiary structures. We use the term “superstructure” to define the even larger functional domains occupied by nucleic acid components in more complex assemblies (e.g. supercoiled chromatin, virus capsids).

2.1 Components and Linkages

The basic structural components of nucleic acids include the sugars ribose in ribonucleic acid (RNA) and deoxyribose in deoxyribonucleic acid (DNA). Both polymers are composed of two or more nucleotides connected by phosphates, which are connected by sugars ribose and deoxyribose, respectively. Each sugar has one attached nucleobase (Figure 1a–d) which connects noncovalently with other strands through base pairing mediated by interbase hydrogen bonds (Figures 2a and b, 3 and 4a–c). The 2' carbon of deoxyribose does not contain

![Figure 1](https://example.com/figure1.png)

**Figure 1** Geometries of a nucleosides in the syn and anti orientation. (a) Adenosine and uridine are in the anti conformation. (b) 8-Bromoguanosine (br8G) and 6-methyluridine are syn owing to their bulky substituents ortho to the glycosidic bond. In br8G, an intramolecular –O5′H–N3– hydrogen bond stabilizes the syn conformation. The C3′-endo sugar puckering is preferred by the anti conformation; C2′-endo is preferred by syn nucleotides. Spheres of increasing size represent H, C, N, O atoms; atomic positions obtained from crystal structure analysis. (c) Nucleotides in the C3′-endo and C2′-endo sugar conformations preferred in A- and B-form DNAs, respectively. The distances between adjacent P atoms in the sugar–phosphate backbone are indicated. (d) Energy map of furanose conformations as a function of pseudorotation phase angle (P). The latter is counted in a clockwise sense with P = 0° in a vertical position. The puckering amplitude (q) corresponds to v_max and increases radially from the central dot representing a planar furanose. The ring indicates the path of true pseudorotation with q = 0.4 Å; filled circles describe energies calculated when all five torsion angles v_i are constrained to the path of pseudorotation; empty circles correspond to only v_3 constrained and other torsion angles relaxed. Note large differences at P = 270° (O4′-exo puckering). Drawn molecules show relaxed geometries and belong to nearest neighbor circles in the energy plot. The nomenclature and orientation are given on the molecule P = 0 (top of circle). Numbers on the diagram indicate energies (kcal mol⁻¹) above global minimum. Saenger, *Principles of Nucleic Acid Structure*, Springer, Berlin, 21, 63, 1984, Copyright Springer-Verlag 1984, and of John Wiley and Sons from D. Voet, J.G. Voet, *Biochemistry*, John Wiley & Sons, New York, 808, 1990.)
a hydroxyl group. This distinction separates the natural nucleic acids into the two major classes, RNA and DNA. The 2'-OH group in RNAs participates in alkali-catalyzed hydrolytic chain breakage, when the hydroxide attacks and binds the adjacent 3' phosphodiester phosphorus and eliminates the 3'-terminal chain. In contrast, DNA, which has a hydrogen at the 2' carbon, is relatively resistant to chain breakage. As a result, the transient functions of RNA rely on its natural tendency toward breakdown.

RNA functions to provide a source of encoded “molecular information” made from the genomic DNA via transcription. Messenger RNA (mRNA) is used to make protein during translation (“gene expression”). The tendency of RNAs to break down allows cells to reabsorb their used mRNAs, leading to genetic “information turnover”. Many, many other functions of RNA have been described. In contrast, DNA functions as a reservoir of relatively stable stored information (like computer permanent memory, ROM) which is decoded during transcription to produce RNA. DNA also participates in replication, to make a daughter genome from the copy provided by the maternal genome, recombination (to swap and reassociate DNA fragments) and many other aspects of genetic metabolism.

The term “glycosidic bond” refers to the covalent linkage between the C1' carbon of the sugar and N1 nitrogen of pyrimidines or N9 of purines, the heterocyclic nucleobases (Figure 2a and b). Sugar “pucker” variants of the pentose rings include C2'-endo and -exo, and C3'-endo and -exo (Figure 1b and c). These conformations can interconvert by the pseudorotation process, in which one atom is viewed as being out of the plane formed by the other four atoms (similar to the appearance of the corner of an envelope) then another atom becomes the nonplanar one, and so on to create a cycle of stepwise conformational exchanges about the periphery of the sugar ring.

The C2'-endo pucker projects the atom out of the plane of the other ring carbons toward the nucleobase. This pucker variant is favored in the structure of B-DNA (Figure 4a) by a few kilojoules per mole over the other predominant pseudorotation variant, the C3'-endo sugar pucker. The C3'-endo sugar pucker projects the C3' carbon out of the plane toward the nucleobase (Figure 1c and d). This conformation occurs in the A-form (Figure 4b) structures adopted by both DNA and RNA. Both types of pucker variants are found within the zig-zagged backbone of Z-DNA (Figure 4c).

The sugar residues of nucleic acids are often modified. For example, in 2'-O-methylated ribose, a methyl group forms an ether linkage, sharing the hydroxylate oxygen with C2'. Sugar modifications are found in transfer RNAs (tRNAs) and in the C/D box of small nucleolar RNA (snoRNA). The snoRNAs are used to specify sites for enzymatic methylation of nucleolar rRNAs to the methylase(s).
have been produced for biotechnological applications. Structural transformations.

Mono- and polyatomic cations bind to this feature of the phosphate backbone are deprotonated, producing a negatively charged backbone, with one anionic site per nucleotide. This polyanionic nature of nucleic acid structure plays a predominant role in the physical, chemical and functional properties of these biomacromolecules. Mono- and polyatomic cations bind to this feature of the external surfaces of nucleic acid structures, modulating their stabilities and sometimes inducing significant structural transformations.

Synthetic modifications of the phosphate backbone have been produced for biotechnological applications. The nucleobase sequence confers structural specificity and uniqueness to a given nucleic acid. There are two general classes of nucleobases, purines and pyrimidines. The bulky bases, adenine (A) and guanine (G), are found in both DNA and RNA. In canonical Watson–Crick (WC) base pairs, these purines form hydrogen bonds with the monocular pyrimidines – thymine (T) in DNA and uracil (U) in RNA – and cytosine (C) (Figure 3).

The second major structural component of nucleic acid structure is the phosphodiester backbone, which joins the nucleotides together (Figures 2–4). The 5′-hydroxylate of one nucleotide is covalently bound to the 3′-hydroxylate of the next “upstream nucleotide” in the sequence. By convention, sequences are always listed from the end with the free 5′-hydroxyl group (the 5′ terminus) to the 3′ terminus, the other end of the (phosphodiester) strand (where i indicates the number of nucleotide residues).

At physiological pH, the exposed hydroxyl groups of the phosphate backbone are deprotonated, producing a negatively charged backbone, with one anionic site per nucleotide. This polyanionic nature of nucleic acid structures plays a predominant role in the physical, chemical and functional properties of these biomacromolecules. Mono- and polyatomic cations bind to this feature of the external surfaces of nucleic acid structures, modulating their stabilities and sometimes inducing significant structural transformations.

Synthetic modifications of the phosphate backbone have been produced for biotechnological applications. For example, in phosphorothioates a sulfur atom is covalently linked by a double bond to the central phosphorus atom, replacing the carbonyl oxygen. As a result, the backbone is nuclease resistant and the nucleic acid has an extended functional lifetime. Methyl groups may also be covalently linked to the phosphate groups in place of the carbonyl oxygen. These methyl phosphate modifications also impart nuclease resistance.

The nucleobase sequence confers structural specificity and uniqueness to a given nucleic acid. There are two general classes of nucleobases, purines and pyrimidines. The bulky bases, adenine (A) and guanine (G), are found in both DNA and RNA. In canonical Watson–Crick (WC) base pairs, these purines form hydrogen bonds with the monocular pyrimidines – thymine (T) in DNA and uracil (U) in RNA – and cytosine (C) (Figure 3).
Modified nucleobases are very common in natural RNAs, especially transfer RNA (tRNA). For example, nucleobases are methylated at all ring positions. Two common RNA base variants, pseudouridine and dihydrouridine, occur in all tRNAs. Pseudouridine is a U that is attached to ribose at C5 instead of N1. Dihydrouridine is structurally similar to uridine, except the aromatic ring is saturated at the 5,6-π-bond, making dihydrouridine much more flexible than uridine. Dihydrouridine is always present in tRNA (at position 17) and common in small nuclear and nucleolar RNAs. More complex modifications, composed of isopropyl groups, amino acid side chains, and many others, have been described. A particularly useful example, the three-ringed G derivative wyebutine, allowed early researchers to isolate phenylalanyl transfer RNA (tRNA Phe), by virtue of derivative wyebutine, allowed early researchers to isolate phenylalanyl transfer RNA (tRNA Phe), by virtue of G derivative wyebutine, allowed early researchers to isolate phenylalanyl transfer RNA (tRNA Phe), by virtue of.

Modified nucleobases occur in many nucleic acid species. The RNA nucleobase U is methylated to form the DNA base (T, really m5U). The content of the developmentally important modified base 5-methylcytosine (m5C) differs in the chromosomal DNAs of wild-type and diseased cells. A more complicated modification, found in some bacterial virus DNAs, involves covalent attachment of a glucose ring to a C5-hydroxyl group on C. Another example involves enzymatic methylation of a N1, which is required to protect the duplex DNA from restriction enzyme cleavage.

RNAs, especially transfer RNA (tRNA). For example, nucleobases are methylated at all ring positions. Two common RNA base variants, pseudouridine and dihydrouridine, occur in all tRNAs. Pseudouridine is a U that is attached to ribose at C5 instead of N1. Dihydrouridine is structurally similar to uridine, except the aromatic ring is saturated at the 5,6-π-bond, making dihydrouridine much more flexible than uridine. Dihydrouridine is always present in tRNA (at position 17) and common in small nuclear and nucleolar RNAs. More complex modifications, composed of isopropyl groups, amino acid side chains, and many others, have been described. A particularly useful example, the three-ringed G derivative wyebutine, allowed early researchers to isolate phenylalanyl transfer RNA (tRNA Phe), by virtue of derivative wyebutine, allowed early researchers to isolate phenylalanyl transfer RNA (tRNA Phe), by virtue of.

A particularly useful example, the three-ringed G derivative wyebutine, allowed early researchers to isolate phenylalanyl transfer RNA (tRNA Phe), by virtue of.

The sequence of nucleobases is referred to as primary structure. Interactions between nucleotides within the same strand or another strand produce secondary structures. Natural DNA molecules most commonly consist of double-helical (duplex) strand variants (Figures 2–4). In contrast, RNAs usually form complex globular structures more like those found in proteins. RNA structures are typically comprised of stem–loop (hairpin) pairings, a common subdomain, formed when a strand pairs with itself and “loops out” a region (Figure 5a–d).

The primary energetic contributions to RNA folding result from the “hydrophobic effect”, as found for globular proteins structures. However, “despite the obvious analogies between the folding of proteins and RNA, key differences remain. An important factor in the folding of RNA is that condensation of a polyanion is necessarily sensitive to differences in ionic strength, as the electrostatic repulsion along the backbone provides a strong opposing force to the collapse of hydrophobic bases. Nearly all complex RNAs require Mg2+ for biological activity, both to stabilize the native structure and help mediate catalysis. Magnesium binding is cooperative and coincides with the formation of tertiary structure.

Kinetic studies have suggested that RNA folding can occur sequentially, following a defined pattern. The “folding funnel” concept captures the idea that polymers fold by descending down an energy gradient. Folding is depicted symbolically as one or more “funnel spouts” with different “energy topologies”. The shape indicates the relative intrinsic propensities of chains to fold correctly, become trapped in an intermediate conformation(s), remain unfolded, etc.

Small proteins and other RNAs can enhance the rate of RNA folding processes and increase the net stability of
the folded domain. One very important class of stabilizing agents is the counterions, including mono- and divalent cations and organic nitrogen-based polycations, which offset the high anionic charges that would otherwise result in strand–strand repulsion.

2.3 Superstructural Considerations

The most common higher order structure assumed by DNA is the supercoil (Figure 6a and b). Supercoils are induced by and stabilized by negative superhelical torsional stress. This energy source helps, along with the histone proteins, to produce the high degree of compaction necessary to package the genomic DNA within the relatively small volume of the nucleus. Supercoiled structures are found in circular duplexes (i.e. plasmids) or in molecules that are rotationally constrained at both ends, as in the case of chromosomes in vivo, which are segregated into separate scaffold-bound subdomains. Another important class of contributors to the compacted DNA structure is the superhelix, which is formed by the linking (L_k), twisting (T_w), and writhe (W_r) of the DNA double helix. The superhelix is characterized by a right-handed supercoil with six cross-overs.

Figure 6 (a) Description of the interrelation between linking (L_k), twisting (T_w) and writhe (W_r). Unstrained, relaxed B-DNA with 420 base pairs has 42 turns of one strand wound about the other, L_k = T_w = 42 and W_r = 0 (top). If, now, the DNA is held tight at the left end, and the right end is rotated clockwise by six turns so the double helix is partially unwound, L_k and consequently T_w reduce to 36. This DNA can again be circularly closed with L_k = T_w = 36 and W_r = 0, i.e. compared with the above picture, base pairs of six turns are disrupted. Owing to the tendency of DNA to retain the B-DNA form, however, T_w increases to the original T_w = 42 with 420 base pairs. However, since L_k is a topological number, it is constant, L_k = 36 and [in order to satisfy Equation 19-1 in the original publication] the writhe must become W_r = -6, corresponding to a right-handed supercoil (superhelix) with six cross-overs. (b) Sedimentation rate of closed circular duplex DNA as a function of ethidium bromide concentration. Intercalation of ethidium between the base pairs unwinds the double helix. Since the linking number of the circle is constant, this is accompanied by an equivalent increase in the writhe number. As the superhelix unwinds, it becomes less compact and sediments more slowly. At the low point on the curve, the circular DNAs (plasmids) have bound sufficient ethidium to become fully relaxed. As the ethidium concentration is further increased, the DNA supercoils in the opposite direction. The supertwisted appearances in the depicted DNAs have been characterized by electron microscopy. (Reproduced by permission of Springer-Verlag from W. Saenger, Principles of Nucleic Acid Structure, Springer, Berlin, 452, 1984. Copyright Springer-Verlag, 1984, and of John Wiley and Sons from D. Voet, J.G. Voet, Biochemistry, John Wiley & Sons, New York, 820, 1990.)
DNA structure found in the nucleus are the highly electrostatic DNA-binding proteins, especially the histones around which the DNA wraps in approximately 200 base pair segments to form the “beads on a string” motif.\(^1\) Thus, charge neutralization plays a crucial role in accommodating DNA in its natural niche.

3 DNA STRUCTURE

The delineation of the details of DNA and RNA structures has benefited tremendously from X-ray crystallographic techniques, in which highly ordered crystals are formed and illuminated with narrowly collimated X-ray light. The diffraction angles and intensities of spots produced by the light beam are used to calculate distances and angular relations between atoms in the molecular lattice. The crystals have been difficult to produce, so only limited information is available, especially for RNAs. Structures of a moderately large set of duplex DNAs have been determined best exemplified by the very well-resolved dodecamer fragment studied by Dickerson et al.\(^6\) Structures of left-handed DNAs, four-stranded quadruplex DNAs, mismatched and bulged DNA duplexes, a few tRNAs,\(^1\) Group I intron RNA fragments, hammerhead RNAs\(^7\) and some non-WC (mismatched) base-pair-containing RNA duplexes are described below and in the Further Reading section.\(^8\)

3.1 Duplex Structures

RNA and DNA molecules have very different intrinsic structural predispositions. The duplex structure occurs in most native DNAs and RNAs. DNAs are typically duplexes in long strands, whereas RNAs are usually formative subcomponents within more complex tertiary motifs.

The exact conformations adopted by strands in duplex DNA depend critically on sequence, salt and DNA concentrations, temperature and solution conditions (e.g. pH, presence and concentration of apolar or amphipathic solutes, ligands). The most common duplex conformation is the right-handed B-form (Figure 4a). The base pairs are centered on and rotate about the helical axis in a counterclockwise direction; the planes formed by the bases are perpendicular to this helical axis. B-form DNA is found in well-hydrated fiber preparations, as first discovered using X-ray diffraction results obtained by Franklin and interpreted by Watson and Crick.\(^1\) This form predominates under physiological conditions. However, it is now known to occur in equilibrium with sub-helical domains consisting of the right-handed A-forms of DNA and conformations intermediate between
B- and A-forms (Figure 4a–c). Bases in the right-handed A-form helix are skewed slightly away from the helix axis and their planes are tilted about 18° away from it. A-form DNA is preferred in fibers that are less hydrated than those favoring the B-form.

At still lower relative humidity, alternating CG-block sequence DNAs readily adopt the left-handed Z conformation (Figure 4c). This conformation is induced by torsional stress, rotating the nucleotides clockwise about the helical axis. Maintaining the antiparallel strand polarity twists the phosphodiester backbone, producing the characteristic zigzag pattern.

3.2 Triple Helical Structures

DNAs (and RNAs) also form triple-stranded (triplex) structures. Triples can be produced in supercoiled bacterial plasmid DNA of the correct sequence and in promoter sequences of eukaryotic genes.

The triple helix is typically comprised of (pyrimidine)_2 purine base triples in which the N7 face of the WC pyrimidine-purine base pair is associated with another pyrimidine residue (hydrogen bonds are symbolized using a centered bold dot, X·Y). The mode of pairing with the second pyrimidine residue is referred to as a “Hoogsteen interaction” (Figure 7a and b). A number of compatible sequence variants have been described and the predisposition for triplex formation is very dependent on the length.

An interesting well-defined triplex structure is called H-DNA (Figures 8a and b). This structure is characterized by mirror repeated oligopurine or oligopyrimidine sequences that loop a fragment of one strand out and coalesce together. One strand forms a stem–loop and the third of four segments binds to it; the fourth segment is the free loop. H-DNA only forms in extended regions of correct sequences and has been characterized by its susceptibility to S1 nuclease digestion. Although H-DNA maintains a triplex structure, it is comprised of two strands. When the mirror repeat segments coalesce, the axis of the

**Figure 8** Probable structure adopted by the poly(dG)–poly(dC) sequence in supercoiled plasmid DNA and the corresponding hydrogen bonding scheme for the base triplet in the presence (a) or absence (b) of 2 mM Mg^2+. (●) Hydrogen bonds in the non-B-DNA structure; (−−−−) hydrogen bonds in the triplex. (Reproduced by permission of the National Academy of Sciences from Y. Kohwi, T. Kohwi-Shigematsu, *Proc. Natl. Acad. Sci. USA*, 85, 3785 (1988).)
3.3 Four-stranded Structures

G-rich sequences common in telomeric and GC-rich promoter DNAs are highly predisposed to forming four-stranded quadruplexes. Unconfirmed proposals hypothesize that quadruplexes form and contribute to the mechanism of several processes, including the regulation of telomeric interactions, meiotic recombination, DNA methylation, gene expression and viral packaging. Quadruplexes form one-, two- and four-stranded inter- and intramolecular species, paired in both parallel and antiparallel conformations (Figure 10b and c).14,15

The base-pairing motif, a G-quartet, is comprised of four coplanar bases that are hydrogen bonded to form a closed square (Figure 10a). They are right-handed twisted helical structures with anti G glycosidic conformations in most nucleotides, interspersed in some complexes with syn G residues.16

Quadruplexes are stabilized by monovalent cations C+C\textsubscript{H}\textsuperscript{+} base pair formation and mC inclusion.13

Figure 10 (a) “G-quartet” hydrogen bonding scheme. Phosphodiester backbone sugars are indicated by dR. (b) Quadruplexes formed from (i) one, (ii) two and (iii) four strands. Closed circles refer to guanines, small open circles indicate thymines and large open circles represent octahedral coordination complexes involving monovalent cations “caged” within two stacked G-quartets. (c) K\textsuperscript{+}-induced formation of G-quadruplex structure from the corresponding self-complementary WC duplex d(G\textsubscript{4}C\textsubscript{4}). (Reproduced from H. Deng, W.H. Branulin, Biopolymers, 35, 680 (1995). Copyright © 1995 John Wiley & Sons, Inc., reprinted by permission of John Wiley & Sons, Inc., and with permission from R. Jin, K.J. Breslauer, R.A. Jones, B.L. Gaffney, Science, 250, 544 (1990). Copyright 1990 American Association for the Advancement of Science.)
Among monovalent cations, potassium most stabilizes quadruplex formation, associating with the C6 carbonyl oxygens of guanosine residues to form cryptand complexes.\(^{17,18}\) Physiological Mg\(^{2+}\) concentrations decrease the rate of formation of triplexes and increase the dissociation rate.\(^{19}\) Competition between duplex, triplex and quadruplex depends sensitively on the nucleic acid concentration and type(s) and concentration(s) of mono- and divalent cations.\(^{20}\) These folding and multimerization processes have been studied from many perspectives, demonstrating some intriguing properties.\(^{21}\)

The four-stranded i-motif (i-tetrad) structure forms by interdigitation of two C\(\text{G}_{16}\)\(^+\) paired parallel stranded duplexes (Figure 11a).\(^{22}\) G-rich strands can form quadruplexes containing C\(\text{G}_{16}\)\(^+\) and G-quartets.\(^{10}\) The i-motif is an antiparallel tetrad with dyad symmetry that forms at acidic pH.\(^{23}\) Cytidine protonation can occur near, at or even above neutral pH.\(^{24}\) X-ray diffraction analyses showed that monoprotonated C\(\text{G}_{16}\)\(^+\) base pairs form across the center of the helix, pairing the two diagonal pairs of strands, trapping the two duplexes by virtue of their interleaved base pairs, like two diagonally interlocked ladders. Interdigitation of the co-stacked duplexes brings the pairs in van der Waals contact.\(^{25}\)

Intercalation liberates a lot of free energy, producing a very stable structure.\(^{25}\) Both types of four-stranded structures have two narrow minor grooves and two wider major grooves. The phosphate backbones are aligned in very close proximity, especially across the two minor grooves.\(^{23}\)

The i-tetrad can form from a single telomeric strand. Interestingly, there are negligible differences in electrostatic interactions between the i-tetrad motif and the two identical duplexes from which it is comprised.\(^{25}\) RNA cannot form the i-motif because the C2' hydroxyl sterically hinders the intercalated geometry.

Similar to the competition between triplex and quadruplex conformation, duplexes may also change structure

---

**Figure 11** (a) Proposed model of the d(TC\(_5\)) tetrad. Intercalation scheme of the two parallel duplexes. The terminal thymidine residues may not be base paired. There are three axes of twofold symmetry (arrows), one along the helix axis through the center of each C\(\text{G}_{16}\)\(^+\) base pair and two between the central C4–C4 base pairs. Many close van der Waals contacts between sugars give rise to the strong inter-residue H1'–H1', H1'–H2' and H1'–H4' nuclear Overhauser effects (NOEs). The 5' phosphates of C4–C4 are above the bases and the C3–C3 phosphates below. Protons C3 H1' and C4 H2' are separated by only 2.2 Å. (b) Sequence of the immobile junction, J1. The molecule consists of four 16-mer deoxynucleotide strands labeled with arrowheads at the 3'-OH termini. In this study, the 5' termini are unphosphorylated. In the text the duplex branches ("arms") are numbered counterclockwise with arm 1 at the left. Note that three arms (1, 2 and 4) contain three AT base pairs, whereas arm 3 contains four. The octameric duplexes correspond to each of the arms of this structure, and also lack 5' phosphate termini. (Reproduced by permission of Nature, Inc. from K. Gehring, J. Leroy, M. Gueron, *Nature (London)*, 363, 564 (1993) and of John Wiley & Sons from L.A. Markey, N.R. Kallenbach, K.A. McDonough, N.C. Seeman, K.J. Breslauer, *Biopolymers*, 26, 1622 (1987). to a quadruplex configuration (Figure 10c). Long stretches of self-complementary G-rich DNAs form tetrad structures called “eclectic DNA”.

### 3.4 Higher Order Structures

The complexity of DNA structure increases in cruciform DNA (Figure 9b), immobile junctions (Figure 11b), and Holliday junctions (Figure 12).

Cruciform DNA is composed of two DNA strands that have a special arrangement of complementary duplex DNA sequences called “palindromes”. A cruciform forms when duplexes form at both ends while the two intervening strands become unpaired and loop out (Figure 9b). These strands then pair intramolecularly to form two separate hairpins (stem–loops), located external to the two flanking duplexes, forming a molecular cross.

Immobile junctions are composed of four strands which each form a duplex with two strands simultaneously, including pairing between the first and fourth strands to form a cross (Figure 11b). The junction residues form one or more mismatched base pairs. An immobile junction is converted into a cruciform by covalently closing two of the four duplex segments to form hairpin loops. Immobile junctions were designed to understand Holliday junctions, a hypothetical structure proposed to form in the course of genetic recombination. Immobile junctions are structurally constrained and do not “slip” to different pairings. The sum of stabilizing enthalpy contributions due to duplex formation in the arms approximately equals that of the junction. In contrast, Holliday junctions must move freely to produce the paranemic junction, the structure formed when two duplexes intermingle during genetic recombination. In this case, enthalpies ($\Delta H$) of both the arms and junction must be nearly zero to ensure that zipping is facile. This process is mediated by the recombinase proteins.

The recently discovered e-motif has been associated with triplet repeat expansion diseases such as Fragile-X syndrome and Huntington’s disease, one of which causes approximately 20% of juvenile-onset retardation. The syndromes are attributed to overproduction (“expansion”) of triplet repeat sequences, yielding long fragile chromosomal domains. The problematic sequences were found to form hairpins containing distorted helices in vitro. This led to the proposal that such structures also form in the lagging strands of replication forks in vivo.

Polymerase slippage, promoted by hairpin formation, is thought to produce the structural instability and disrupt functions. Cytosines flip out and away from the central axis of the helix, especially in sequences that

---

**Figure 12** Holliday model of general recombination. First, nicks are introduced into a homologous region of each sequence. Subsequent strand invasion, DNA cleavage at the cross-over junction, and sealing of nicked strands results in exchange of the ends of the chromosomes. (Adapted from Prentice-Hall from L. Moran, K. Scrimgeour, H. Horton, R. Ochs, J. Rawn, *Biochemistry*, Prentice-Hall, Upper Saddle River, NJ, 26–25, 1994. Copyright © 1994 Prentice-Hall, Inc.)
accommodate C–C base pairs. These extrahelical bases stress the phosphodiester backbone, distort the helix and induce hairpin formation. The two extrahelical bases fold symmetrically into the minor groove but do not form a base pair. [Note: an analogous “base flipping” mechanism leads to enzymatic methylation of C C5 atoms in duplex DNAs.]

**4 RNA STRUCTURE**

Structures formed by RNAs and DNAs differ by the presence and absence of the C2′-hydroxyl, respectively. Hydroxide ions in basic solutions catalyze hydrolysis and cleavage of the phosphodiester backbone of RNA. Hydroxide removes the hydrogen from the 2′-OH, producing an oxygen anion which then attacks the adjacent phosphate phosphorus, thereby eliminating the rest of the chain. Hydroxides are in solution and bound as inner- and outer-sphere ligands to divalent cations, a common source of catalytic activity in RNA reactions.

### 4.1 Duplex Structures

The most common duplex form maintained in RNA is similar to the right-handed A-form found in DNA. RNA can also form a left-handed conformation in high temperatures and salt concentrations, as well as in low hydration conditions.

Both DNAs and RNAs form stable hairpins, but they are more prevalent in natural RNAs than in natural DNAs. They form when two sequential complementary regions of a strand fold together to produce a double-stranded region, terminated by one looped end and a duplex with either a blunt end, dangling strand or two extending strands (Figures 5a–d, 9b and 13a and b). In most biological examples, the free strands emerge from the duplex and continue into other strand domains. Lone hairpins have been extracted for study by researchers to assess their stabilities, structures and other properties. This general approach has its drawbacks but has led to the determination of many structural details that could not be obtained with their full-length counterparts. DNA cruciform structures contain two hairpins (Figure 9b).

**Figure 13** (a) The proposed secondary structure of the 1542 nucleotide E. coli 16S rRNA based on the comparison of sequences from different species under the assumption that this secondary structure is evolutionarily conserved. The flower-like series of stems and loops forms four domains that are indicated by Roman numerals. The placement of certain features with respect to specific ribosomal proteins and the entire 30S ribosomal subunit are indicated. (b) The sequence of E. coli 5S rRNA showing its proposed secondary structure. (Reproduced by permission of John Wiley & Sons from D. Voet, J.G. Voet, *Biochemistry*, John Wiley & Sons, New York, 916, 1990.)

### 4.2 Substructural Components

Complex RNA structures are described in reference to its substructural components (Figure 5a–d). These substructural components form interesting three-dimensional structures that are important for binding and protein recognition. One very common substructural component is the loop. The stability of hairpins and loops
depends on the size of the loop and number of bases included; those with more negative enthalpic ($\Delta H$) and entropy-dependent contributions ($-T\Delta S$) to the overall Gibbs free energy ($\Delta G$). Large internal loops, composed of two strands with (ostensibly) unpaired nucleotides, are thought to be essential for protein recognition. The smallest stable internal loop could be composed of a single-base mismatch.

Base mismatches can also produce bulged RNA (Figure 5a–d). Molecules with mismatches are less stable than those without mismatches; however, some mismatches are more stable than others. As expected, stabilities of mismatched base pairs are generally less stable than purine-purine base pairs. For example, the $G\cdotA$, $U\cdotU$, and $C\cdotC_H^{\text{H}}$ base pairs are much more stable than $G\cdotG$, $C\cdotA$, $C\cdotU$, $A\cdotA$ or $C\cdotC$ pairs. The $U\cdotU$ mismatch is stabilized by hydrogen bonding between complementary imino form nucleobase functional groups.

In an internal bulge (Figure 5a–d), one or more unpaired bases exist on one strand, sometimes stacked between the two flanking base pairs; in others, the base is excluded from the helix to produce a moderate deformation (it “flips out”). The fate of the unpaired base depends on the surrounding sequences; pyrimidines tend to move away from the axis, whereas purines can remain extrahelical or intercalate, depending on the context and solution conditions. Phosphates in bulged strands are extremely close together, producing an anionic domain. In one example, the anionic charge of the closely grouped phosphate oxygens interacts with two Mg$^{2+}$ ions to stabilize the bulge. Bulges and loops are similar in that they are more constrained than single-stranded molecules. As hairpin loops increase in size, their constraints decrease progressively toward those of lone strands.

Figure 14 (a) Nucleotide sequence of yeast tRNA$^{\text{Phe}}$ folded (left) into secondary “cloverleaf” and (right) into tertiary “L-shaped” arrangements. Invariant bases in class I tRNA are indicated by circles; those which are semi-invariant are enclosed in parentheses. WC-type hydrogen bonds in stem regions are marked by dots and the $G\cdotU$ “wobble” pair (G44U69) by a small circle. The number of nucleotides in variable loop V and in $\alpha$ and $\beta$ regions can vary, depending on the tRNA species. Bases forming tertiary base–base hydrogen bonds are connected by thin lines. Note that most of the invariant and semi-invariant bases are positioned in the middle and hinge regions of the “L” and involved in tertiary hydrogen bonds which, together with base stacking, illustrates which parts of the “cloverleaf” join together to form the two legs of the L. (b) Illustration of base-pairing and stacking interactions in yeast tRNA$^{\text{Phe}}$. Base pairs stabilizing secondary and tertiary structure are drawn as bent or fused slabs or by connecting two slabs with rods. Invariant and semi-invariant bases cluster in anticodon loop, CCA end of acceptor stem, and at outer corner and hinge regions of the “L”. Note stacking of bases 34–38 in the anticodon loop, consisting of the anticodon 2′-O-methylguanine (Gm)43–A35–A36. [Circled letters a–g indicate where base pairs and triplets displayed in Figure 15-4 in the original publication are located.] (c) Schematic representation of the $\pi_3$-turn situation in anticodon and T loops of yeast tRNA$^{\text{Phe}}$. Sugars and phosphate groups are simplified as large and small spheres, respectively; bases as slabs; base pair interactions by a bar; H represents hypermodified base. Semi-invariant and invariant bases are stacked with the base pair at the top end of the loop, and the bases at the bottom of the anticodon loop are again stacked with the bases to the right. Phosphates are actively engaged in the turn and form hydrogen bonds and stacking interactions. (Reproduced by permission of Springer-Verlag from W. Saenger, Principles of Nucleic Acid Structure, Springer, Berlin, 332, 335, 339, 1984. Copyright Springer-Verlag 1984.)
4.3 Higher Order RNA Structures

Substructural components interact to form higher order structures. For example, the amino acid acceptor stems and anticodon stem–loops of tRNAs form an L-shaped tertiary structure when the other two stem–loops fold together to form a kind of “glue” that stabilizes the “joint” region of the L (Figure 14a–c). Structure is one of the defining components of function and is intimately related to sequence. Strands composed of different sequences can sometimes form similar secondary structures. In fact, in a few known cases secondary structures can adopt similar tertiary structures. The anticodon bases of tRNA jut away from the rest of the loop and can interact with ligands (Figure 14a–c). The anticodon loop bases can convert between the “3'-stacked” and “5'-stacked” structures, in which the nucleotides in the loop align above either the 3'- or 5'-terminal strand of the attached duplex stem. Although the anticodon region of tRNA is single-stranded, its bases stack and thus stabilize the extended exposed face of the trinucleotide, which facilitates codon recognition and decoding. Another stabilizing structural component of the anticodon is the U-turn, in which U33 interacts with the phosphate of residue U37 (Figure 14c). A wealth of different base assemblies occur in tRNAs, forming a large percentage of our lexicon of RNA substructural components.

Pseudoknots are a common higher order structural motif in natural RNAs. In these structures, the loop of a hairpin binds to a complementary sequence adjacent to the sequence that forms half of the stem of the hairpin (Figure 15a and b). Unlike U-turns, pseudoknots do not occur in tRNAs. The ability of the pseudoknot structure to bend is affected by steric hindrance between nucleotides that comprise the two entangled loops. The structure is compact, not elongated, resembling a moderately extended globular protein. Because the pseudoknot is comprised of two smaller hairpin substructures, the RNA molecule can form two different hairpins with either a 5'- or 3'-terminal “dangling end”, depending on their respective free energies (Figure 14a–c). Transitions between these two structures depend on both base sequence and salt concentration.

Pseudoknots are thought to regulate transcription, possibly controlled by cation concentration fluxes, protein

Figure 14 (Continued)
recognition or both. They can mediate protein recognition by forming structures resembling tRNA acceptor stems. For example, this occurs at the 3′-termini of some plant viral genomic RNAs (e.g. tobacco yellow mosaic virus). In this case, two different secondary structures, viral pseudoknots and tRNA stems, form similar tertiary structures. The 3′-terminal hydroxyl group of the viral RNA is aminoacylated by the "cognate" aminoacyl tRNA synthetase, forming a protective genomic "cap" that prevents exonucleolytic digestion.

Ribosomal recognition depends on sequentially binding similar, but subtly distinctive, tRNA anticodon and mRNA codon structures formed as the mRNA is processed by the ribosome and read by tRNA. This normal process can be subverted in several known ways. For
example, a suppressor tRNA skips (reads through) a stop codon by inserting an amino acid (commonly tyrosine) into the nascent protein chain instead of terminating protein synthesis.

In another situation, translating ribosomes can pause when the mRNA is allowed enough time after its transcription to form a certain stem–loop structure. The time-frame of the pausing event depends on the stability of this hairpin. The phenomenon is the basis for translational attenuation, in which amino acid starvation results in the absence of that aminoacylated tRNA. During this duration, one type of folded stem–loop motif forms and translation continues. To ensure that the anabolic enzyme needed to produce this amino acid is made, sufficient “charged” aminoacyl tRNAs must be available to translate the leader sequence codons. If stalling lasts long enough, an alternatively folded hairpin forms and translation is aborted. The amino acid concentration, titrated by the time-frame of transcription and movement of tRNAs through the ribosome, determines whether protein is made or not.

Translational frameshifting occurs when ribosomes pause preferentially at internal sites on the decoding mRNA strand. When a translating mRNA forms a pseudoknot, the ribosome pauses much longer at that site. This increases the degree of “slippage” in base pair alignment between tRNAs and the reading frame of the mRNA, making a frameshift possible. One such example occurs during translation of the mouse mammary tumor virus genome, in which alternative viral proteins are encoded in different overlapping reading frames (Figure 15c). Pseudoknot formation produces a (−1) nucleotide frameshift and, as a result, alternative proteins.

The recently identified A-platform structure was determined by X-ray crystallography (Figure 16a–c). This large RNA fragment forms a catalytically active subregion which was extracted from the much larger Tetrahymena Group I intron structure. This fragment is important because the residues in the vicinity of the A-rich bulge are essential for ribozyme activity. The A and flanking residues bind a string of Us in a second domain formed by distant primary sequence residues. This “docking” interaction links distantly separated sequences via base pairing. A “GNRA tetraloop” subfragment binds the A-platform, termed its receptor, and as a result produces a tertiary structural motif composed of a stem fragment “super-looped” back on itself and adhered to a distant stem with an intervening bend region. The platform undergoes a large conformational change in the absence of this tertiary interaction. The A-platform is stabilized more by base stacking forces than hydrogen bonding, but both contribute.
Many of the stem loop sequences in known RNA folds contain consensus GNRA tetraloop sequences. Ribosomal RNA secondary structures have been predicted from sequences obtained from organisms spanning a broad range of phylogeny. Sequence requirements for the unique stabilization are very specific and clearly linked to binding interactions between the participating residues. The initial G base and final A phosphate form a hydrogen bond and the N7 atom of the third purine (R) forms a hydrogen bond with the sugar hydroxyl hydrogen at the N position, which can therefore be any nucleotide. The second nucleotide is not specifically involved in stabilizing the structure. These more stable tetraloops are thought to play a key role in the tertiary folding of large RNAs. Reverse transcriptase stop sites often contain this sequence.

Another unique example of RNA tertiary structure is formed when two hairpin loops dock to produce “kissing hairpins”, the evolutionarily conserved motif formed by genomic human immunodeficiency virus (HIV) RNA. The HIV genome is comprised of two identical positive sense RNA strands. Hairpin loops at the 5′ ends of each molecule promote genomic dimerization in vitro and are required for viral packaging in vivo. RNA quadruplex formation by two condensed HIV genomes has also been proposed to mediate viral packaging.

The hammerhead RNA motif is functionally and structurally similar to the Group I intron fragment. The three stems in the hammerhead ribozyme form a three-way junction (Figure 5d); the nucleotides all maintain the anti configuration. Hammerhead RNA is thought to mediate RNA processing, catalyzing specific cleavage and maturation of the initial RNA transcript. Structural formation and enzymatic activity require the presence of divalent cations, primarily Mg2+ in vitro, although other cations (and some of the transition and posttransition metals) function in a similar fashion. They are thought to act as Lewis bases, increasing the local OH− concentration and possibly directing reactants into the precise tertiary structure(s) essential for cleavage.

Hammerhead RNA cleavage has been characterized using Michaelis–Menten kinetics. Reaction rates depend on reactant and product concentrations and pH values. Cleavage does not occur below pH 5, most likely because required nucleotides are protonated. The reaction rate increases until pH 7 is reached, then decreases rapidly. Cleavage does not occur at higher temperatures. Since proper tertiary structure formation is so essential, the destabilization that occurs at higher temperatures probably short-circuits the reaction mechanism.

5 ENERGETICS

The numerous examples described so far clearly illustrate that the structures, functions and energetics of nucleic acids are intricately linked. Many techniques and strategies have been developed to study these relationships quantitatively, each emphasizing different aspects of detected properties and/or functional groups of the nucleic acid under investigation. These structural entities range from individual bonds to moderately sized complexes (e.g. duplexes) to large structures, such as superhelically stressed plasmid DNAs. One strategy used to study these problems is to “divide and conquer”. Studies define facets of a problem in a piecewise fashion in the hopes of using the resulting information to solve problems involving the structure within its overall context. As previously outlined, the smallest complex substructure is the base pair. Adjacent base pairs affect the stability of each other. Nucleotides on both sides contribute when a base or base pair is embedded within a duplex, producing a sequence-dependent synergism. This additivity is called and modeled mathematically as the “nearest neighbor effect”.

Interbase orbital overlap is optimized within the constraints otherwise available to the aggregated domain as a result of the hydrophobic effect. Dipole–dipole London dispersion forces also participate in stabilization, but knowledge regarding relative contributions is not precise. Theoretical calculations support the expectation that large subdomains form synergetically. Quantum mechanical energies and van der Waals forces require including structures up to at least a 15 Å distance away from a particular atom to achieve self-consistency. Individual base pairs affect those around them and vice versa.

5.1 Thermodynamic Characterization

The most common method to characterize the energetics of nucleic acids in the context of structure involves measuring equilibrium thermodynamics. The net spontaneity of a reaction is characterized by ΔG, but only if the mechanism is rapid compared with the scan rate of the melt temperature-ramping process. The familiar result is that more stable interactions have more negative free energies. In the usual vernacular, the process (e.g. structure formation) is more spontaneous. An important characteristic of ΔG is its logarithmic proportionality to the equilibrium constant and its dependence on temperature, characterized by the fundamental equations [Equations 1 and 2]. Reactants must attain enough energy to pass the transition state to form products.

\[ \Delta G = \Delta H - T\Delta S \]  
\[ \Delta G = -RT \ln K \]
Both $\Delta H$ and $\Delta S$ contribute significantly to the net $\Delta G$ of many duplex denaturation–renaturation reactions. These parameters characterize sequence-dependent stabilities of intra- and intermolecular nucleic acid complexes. Their relative contributions demonstrate many subtleties regarding interdependences between molecular energies, structures and solvent components. In many cases, they give important insights into the relations between structures and functions. In this account, we generally only list qualitative comparisons or trends found, especially focusing on how the parameters depend on the relevant variable(s) (but many quantitative results are cited in the Further Reading).

Base stacking is one of the predominant driving forces behind the maintenance of nucleic acid structure. The partially hydrophobic bases stack with one another to minimize interaction with the surrounding solution and each other (Figure 17). As expected, the more hydrophobic purines stack with more stability than pyrimidines. Stacking ability depends on the electron distribution of the rings and their exocyclic components. Disrupting the stacked structure is usually accomplished by raising the solution temperature, leading to thermal denaturation (melting). Less stacked or unstacked random coil structures are rarely found, except at elevated temperatures or under relatively destabilizing conditions (i.e. in lower polarity solvents or in 7 M urea).

Hydrogen bonds also play a major role in stabilizing nucleic acid structure. In fact, helix structures literally revolve around them. Exocyclic protons and lone-pair electron components on opposing bases form these complementary interactions. To a reasonable approximation, relative stabilities and flexibilities of different structures are determined by hydrogen bonds. Their strength depends critically on interatomic distance and orientation, with linear alignment of the three atoms being optimal. Since G-C base pairs have three hydrogen bonds, they are stronger than A-T or A-U base pairs, which only form two. Relative stabilities correlate with the number of hydrogen bonds. Since both G and C are more hydrophobic than A and T (and less hydrophobic U), stabilization is also correlated with less polar components.

Figure 17 (a) Base-pair and base-step parameters of nucleic acid double helices. The structures of double-stranded nucleic acids are defined by the relative conformations of two adjacent base pairs in a base step (e.g. helical twist, roll, tilt, rise and slide) and the relative conformations of the bases in a base pair (e.g. the propeller twist). (b) Illustration of “Calladine’s rules”. (i) Adjacent G-C base pairs in a DNA double helix, with positive propeller twist, display sequence-dependent interactions between guanines on opposite polynucleotide chains. (Top) The sequence pyrimidine-$(3',5')$-purine leads to clashes in minor grooves (open arrow), whereas the purine-$(3',5')$-pyrimidine sequence (middle) causes clashes in the major groove. Clashes can be avoided by reduction of propeller twist, opening up the roll angle $\theta_R$ (bottom), reduction of helical twist (h) shown in (c), or shifting base pairs such that the purine (guanine) is pulled out of the helical stack [shown in (ii)]. (ii) The purine–purine clash displayed in (a) can be reduced by shifting the G-C base pair laterally, which pulls the G out of the helical stack (arrow). In order to maintain similar helical P–P distances, sugar puckers are changed, yielding a larger $\delta$ angle for purine and a smaller one for pyrimidine. Associated with these changes are $\chi$ rotations, as required for the “autocorrelation principle” [section 11-2 in the original publication]. Increase of helical twist from $36^\circ$ to $45^\circ$ (top) shortens the distance between N3 atoms in the minor groove (top), whereas reduction to $27^\circ$ (bottom) widens this distance. If coupled with a positive propeller twist, N3 atoms in the top base pairs (heavy lines) move down (indicated by minus signs), those in the bottom base pairs (light lines) move up, leading to unfavorable N3–N3 clashes. These clashes are diminished by helical untwisting to $27^\circ$ (bottom). (Adapted from Prentice-Hall from K. Van Holde, W.C. Johnson, P.S. Ho, Physical Biochemistry, Prentice-Hall, Upper Saddle River, NJ, 56, 1998. Copyright © 1998 Prentice-Hall, Inc., and of Springer-Verlag from W. Saenger, Principles of Nucleic Acid Structure, Springer, Berlin, 254, 255, 1984. Copyright Springer-Verlag, 1984.)
Enthalpy changes can be determined indirectly via Van’t Hoff analysis or directly using calorimetric approaches. Van’t Hoff approaches monitor the properties of a certain substructure as they change (Figures 18a and b, 19a and b and 20). One must find conditions suitable to measure the equilibrium constant of a reaction as a function of temperature. The melting behavior of nucleic acid complexes is sensitive to its strand number, its molecularity \((n)\). The Van’t Hoff enthalpy \((\Delta H_{\text{VH}})\) is calculated using Equation (3):

\[
\Delta H_{\text{VH}} = (2 + 2n)RT_m^2 \left( \frac{\partial \alpha}{\partial T} \right)_{T=T_m}.
\]  
(3)

The “melting temperature” \((T_m)\) refers to the temperature at which the concentrations of single (melted) strands and paired structures are equal, the midpoint of the equilibrium, and \(\alpha\) is the extent of the reaction. The term \(T - T_m\) indicates the temperature range studied to probe the reaction equilibrium. For species with \(n > 1\), the equilibrium poise is strongly dependent on the strand concentration, adding more shifts the poise toward the products.\(^{32,39,40}\) Increasing the temperature dissociates the strands. The breadth of the \((1 - \alpha)\) vs \(T\) curve is an indication of the degree of cooperativity of the transformation. Zipper models capture the image well; initial pairings facilitate subsequent pairings (positive cooperativity). Both duplex assembly and melting are relatively (positively) cooperative. Increased ionic strength and cationic polyanines and proteins increase the cooperativity.\(^{39,43,44}\)

5.2 Calorimetric Determination of Enthalpies

Calorimetric methods also provide an approach to obtaining information about the enthalpy changes associated with structural transformations, ligand binding, etc. The change in heat capacity \((\Delta C_p)\) is determined calorimetrically by scanning across the same range of temperatures used for the UV spectral melt data acquisition, then integrating the resulting derivative plot [Equation 4]:\(^{40}\)

\[
\Delta H^\circ = \Delta C_p \, dT.
\]  
(4)

The differential scanning calorimetry (DSC) apparatus scans through the temperature range encompassing the structural transition slowly enough to ensure that the strands equilibrate at each intermediate temperature.\(^{39}\) DSC enthalpies should be equal to those calculated by
Figure 18 (a) Schematic representation of a thermally induced transition from a fully base-paired and base-stacked double helix to two unpaired and unstacked single strands. (b) (i) Schematic of an optical density (O.D.) vs temperature profile (a UV melting curve) showing the hyperchromic effect associated with a transition from a base stacked (helix) to an unstacked (coil) state. (ii) A derived melting curve showing the fraction in the coil state \(1 - \alpha\) as a function of temperature. The two figures together illustrate how the experimental absorbance vs temperature profile can be converted into a \((1 - \alpha)/N\) versus temperature melting curve. (Reproduced by permission of Springer-Verlag from K.J. Breslauer, in Thermodynamic Data for Biochemistry and Biotechnology, ed. H.-J. Hinz, Springer, New York, 405, 1986. Copyright Springer-Verlag 1986.)

Figure 19 The shape of the derived \((1 - \alpha)\) vs temperature melting profiles for (a) cooperative and (b) noncooperative transformations. Noncooperative transitions have broader melting profiles and \((1 - \alpha)\) vs temperature curves with reduced \((\partial \alpha/\partial T)\) slopes at the \(T_m\) (below). This results in a lower value for the transition enthalpy. (Reproduced by permission of Springer-Verlag from K.J. Breslauer, in Thermodynamic Data for Biochemistry and Biotechnology, ed. H.-J. Hinz, Springer, New York, 408, 1986. Copyright Springer-Verlag 1986.)

Figure 20 Typical plots of the concentration dependence of the melting temperature. When plotted as \(1/T_m\) vs log \(c\), the slope is equal to \(R/\Delta H\) and the intercept is equal to \(\Delta S/\Delta H\). At any temperature, the horizontal distance between the two lines \((\Delta \log C)\) is proportional to the free energy difference between the two self-complementary oligomers as described in the text. (Reproduced by permission of Springer-Verlag from K.J. Breslauer, in Thermodynamic Data for Biochemistry and Biotechnology, ed. H.-J. Hinz, Springer, New York, 151, 1986. Copyright Springer-Verlag 1986.)

van’t Hoff analysis if one applies the correct molecularity. For example, \(n\) was calculated from calorimetric and spectroscopic data obtained with the quadruplex DNA formed by d(G2T5G2)i n1MN a C l .\(^{17}\)

Entropy is related to the degree of disordering open to a molecule, which is modeled mathematically by enumerating the number of possible statistical variations of a “system” and stipulating the population distributions among them. These distributions could characterize a set of different molecular conformations, orientations or interactions between functional groups or more than one molecule. They could also include their interactions with ligands or solvent.

Water contributes in a particularly important way to entropy changes of biomolecules.\(^{11,42,46}\) The stability of nucleic acid structural aggregates is strongly influenced by hydrophobic interactions involving buried and exposed residues and the surrounding solvent. The energy associated with the cage of water molecules surrounding the structure is governed by both entropy and enthalpy; the dominant contribution changes with increasing temperature. At temperatures \((\leq 60^\circ C)\), hydrogen bonds (enthalpic contributions) interconnect the surrounding
H₂O molecules and “encage” the more hydrophobic nucleic acid, forcing it to fold into the native structure. When the temperature is increased above ca. 60 °C, vibrational fluctuations overcome the hydrogen bond energies, the cage H₂O molecules dissipate and the nucleic acid denatures. Enthalpic contributions to folding energies dominate at lower temperatures; the ΔS associated with H₂O randomization and release dominates at higher temperatures. A similar situation governs equilibria associated with protein folding and membrane assembly.

5.3 Spectroscopic Techniques

As discussed previously, UV absorbance spectroscopy is commonly used to study the thermal denaturation behavior of nucleic acids (Figures 18–21). 1,30,39 This method allows one to study temperature-dependent dissociation (melting) and association (hybridization) behaviors, conformational changes and ligand binding. The large extinction coefficients of the nucleobases allow one to perform studies with relatively low sample concentrations (micromolar to millimolar). The molar extinction coefficients of individual bases decrease when the bases stack, a phenomenon called the hypochromic effect (Figures 18 and 19). UV spectroscopy allows one to monitor the course of temperature-dependent transitions by studying the ratio of stacked to unstacked bases. The total absorbance of the disrupted structure is larger than the sum of the absorbances of each individual nucleotide. Denaturation by melting the stacked bases produces an increase in the absorbance at 260 nm, allowing one to obtain quantitative energetics, usually by studying the concentration dependence of T_m (Figure 20).

The sequence of a nucleic acid influences the stability of the strand in a base-paired secondary structure. Contributions to stabilization by stacking interactions, resulting from different nearest neighbor free energies, determined for a set of DNA sequence variants, are shown in Table 1. Similar data obtained with RNA variants are shown in Tables 2 and 3. These nearest neighbor stacking energies provide a method to estimate the stabilities of RNA or DNA duplexes (Figure 21). This information has been used extensively to predict the most energetically likely secondary structures (e.g. Figures 13–16). While these predictions are useful, they are only approximations and must be interpreted cautiously. For example, slow reaction kinetics can lead to invalidation of the equilibrium assumption upon which the analysis is based.

Secondary structures are also predicted from evolutionary sequence conservation data. Biological sequences remain similar over time and large portions of genomes often exhibit cross-species similarities. Therefore, it is inferred that they maintain similar structures. Promoter region sequences of genes, GpC islands, centromeres, telomerases and other repetitive sequences (SINES, LINEs, Alu sites) are often evolutionarily conserved.16,47 Slight changes in sequence (and as a result structure) may produce changes in gene expression or RNA-mediated functions. Mutations do not typically affect the functions of DNAs, RNAs or their encoded proteins. Although usually quiescent, the mutant RNA or protein structure may contain interactions or adopt structures with severely compromised functions, resulting in dire health consequences. Many of the modern approaches to studying disease revolve around the protein aspect of this
A more complicated absorption property of nucleobases, their interaction with circularly polarized UV light, has been used extensively to study nucleic acid structures and interconversions. The circular dichroism (CD) spectrum, obtained with a spectropolarimeter, is a plot of the difference in absorbance of negatively (right) and positively (left) circularly polarized light as a function of the wavelength range studied.\(^{(1,45,48)}\) This difference is very sensitive to the detailed chirality of stacked and interacting base assemblies and their structural changes. Many structural transformations, ligand binding reactions and chemical modifications (e.g. with covalently reactive mutagens) have been characterized.\(^{(49)}\) Nucleic acids become more chiral when a helix forms and less so when it denatures. When information can be acquired by using other techniques that yield structures [i.e. molecular coordinates; e.g. X-ray crystallography or NMR] or about specific bond motions (e.g. NMR, Raman scattering spectroscopy), CD results can be used to great advantage to study changes between two or more previously characterized states. The more qualitative CD technique is sensitive and easier, allowing one to characterize a much more extensive range of variables.

IR and Raman spectra are sensitive to vibrational motions of specific functional groups and are used to study the stretching and bending frequency modes of molecules. IR and Raman methods allow one to study interactions between functional groups, e.g. to monitor the formation and loss of hydrogen bonds. Bond formation and dissociation change the frequency of the absorption (or scattering) peak, allowing detailed analysis of bond changes in nucleic acid and between them and proteins, ligands, etc.

Raman and IR spectra provide complementary information about the active types of vibrational modes predominant in the absorptive functional groups being monitored.\(^{(1,45,48)}\) The bond is the chromophore. For example, Raman spectroscopy was used to study the assembly and disassembly of DNA quadruplexes formed...
by one or two strands, demonstrating that the mono- and bistranded complexes depend differently on Na+ and K+ concentrations. Raman scattering works better than IR to characterize most aqueous samples. Atoms can move in a symmetric scissors motion (toward and away from each other within the plane formed by the three atoms). Asymmetric wagging fluctuations (of the two bonds with respect to each other) are also possible. In the symmetrical motion analogy, one scissor blade can either close when the other closes or opens simultaneously. In the asymmetric case, the motions of the bonds occur in two planes that are skewed with respect to each other and at frequencies that are not correlated in time. Only symmetrical shifts are active (observed) using IR spectroscopy. Molecules with complex conformational constraints rarely maintain perfectly symmetrical motions, so Raman scattering can be used to study functional groups that fluctuate predominantly via symmetrical motions, but also have these imperfect symmetrical stretches. Raman spectroscopy is relatively sensitive and has a key advantage relative to IR. Peaks normally observed using IR are obscured by the dominant symmetrical stretch motion of solvents such as water. Water is less Raman active and can usually be filtered out using deuterium oxide, allowing visualization of most functional group peaks. Structures and dynamics of nucleic acids have been characterized in systems ranging from nucleotides to duplexes to viral genomes in packaged virus particles. Interactions, motions and assembly–disassembly phenomena have been elucidated.

NMR has also provided a wealth of structural and dynamic information about nucleic acids. 1H-NMR has been used to study protons; 31P-NMR provides information about the backbone phosphorus atoms and connected structures. 13C-NMR has been used to study skeleton carbons; 15N-NMR has yielded information about amino and imino NH groups. All of these isotopes, in addition to deuterium, are used in various multidimensional NMR experiments to assign peaks by characterizing through-bond interconnectivities. Spectroscopic relaxation studies with 1H, 13C, and 15N-labeled molecules have been used to probe fluctuational motions, their spatial magnitudes and timescales. The 1H–1H nuclear Overhauser effect (NOE) and scalar J-coupling methods allow one to determine the frequencies (chemical shifts) of peaks of specific hydrogen atoms and determine calibrated distances between these assigned atoms. Three-dimensional structures are determined by reconstructing spatial connectivities between neighboring hydrogen atoms.

Problems associated with simultaneously stipulating structure and the ranges and frequencies of molecular motions, when many different types of motion are occurring, complicate calculating structures. Full matrix data analysis techniques and molecular mechanics/dynamics simulation protocols have been developed to do so, but information is limited so far (some examples are described in the Further Reading section).

5.4 Electrophoretic Techniques

Electrophoresis separates molecules, structures and/or complexes based on different charges and size-dependent properties. Larger molecules and plasmids are separated on agarose gels; moderately sized and smaller molecules are resolved on polyacrylamide gels. The electrophoretic mobility decreases with the size (charge) of the negative nucleic acid backbone. High-percentage polyacrylamide gels (ca. 20%) can separate oligo- and polynucleotides ranging up to ca. 500 nucleotides in length, differing by only one nucleotide, termed single-base resolution in sequence determination. This has allowed the molecular characterization of many sequences, ligand binding sites, complex formation reactions, mutagen action scenarios and other reactions. The results are always based on how the process of interest alters the size and/or charge of the nucleic acid fragments under study. The chaotropic solute urea is typically used to denature nucleic acids in gels. Native structures and complexes have been studied extensively. For example, protein binding decreases the mobilities of bound nucleic acids, the basis of the mobility shift technique.\(^{54}\)

Electrophoretic techniques have been used to understand the effects of superhelical stress on the supercoiling behavior of DNA. Supercoiled closed-circular plasmid DNAs are more mobile than relaxed plasmids because they are smaller hydrodynamic particles. Introducing negative supercoils while maintaining the B conformation introduces torsional strain; adding a single negative supercoil increases \(\Delta G\) (at 25°C) for duplex formation by about 38 kJ mol\(^{-1}\). Thermodynamic stress is relieved by induction of Z-DNA and cruciform formation. Extremely large amounts of DNA are present in the small volume of the nucleus. The DNA packaging process requires a large amount of torsional stress.\(^{55}\)

Such molecules have traditionally been modeled as ordered condensed double helices. Aged cells contain significant amounts of damaged aggregates. Nucleic acids are recycled when cells undergo apoptosis (programmed cell death), degraded by Ca\(^{2+}\)/Mg\(^{2+}\)-containing nucleases.

Electrophoresis has been used to determine how topoisomerases relax and induce torsional stress by catalyzing induction and/or relief of supercoiling. Topoisomerases are essential for DNA replication and transcription, since torsional stress must be relieved in order to unwind the double helix. Topoisomerase I relaxes torsional stress by cutting only one strand in duplex DNA and rotating the freely dangling ends in opposite directions around the axis of the uncut strand. Topoisomerase II enzymes (DNA gyrases) can introduce negative supercoils by introducing double-stranded breaks, then resealing the backbones. Since the number of rotations prior to resealing vary in a stepwise (integer) pattern, one obtains a family of discrete topoisomers. The individual topoisomers can be separated and the energies associated with their interconversions quantitated using a two-dimensional gel electrophoresis technique involving the use of the intercalative molecule chloroquine.\(^{56,57}\)

Electrophoretic analyses of products generated using more traditional methods involving chemical reactivity and enzymatic recognition have also been used to determine how a broad range of intercalators affect the structure and energetics of DNAs and RNAs. Intercalation involves stacking of a planar aromatic molecule (e.g., ethidium bromide) between two base pairs, thereby increasing the length of double-helical DNA.\(^{1}\) This distortion can result in mistakes in replication which may produce genetic mutations. Since intercalators relieve superhelical stress, the hydrodynamic volume of a plasmid increases, decreasing its electrophoretic mobility.

DNA can form higher order structured aggregates. One example of a noncytoplasmic, minimally soluble, DNA state forms when DNAs and RNAs packed inside viral particles to form condensed aggregates. Topological stresses in such situations are not well understood. Structures have been studied using low-resolution electron microscopy, low-angle X-ray scattering and Raman spectroscopy approaches. Model structures called P-DNA and \(\psi\)-type DNA have been developed based on CD, linear dichroism and CD scattering results. Left-handed Z-DNA duplexes can form multistranded, torus-shaped macroaggregates which have been characterized using electron microscopy.

Temperature gradient gel electrophoresis is another example of a method that can be used to determine the melting behavior of a nucleic acid structure. One determines the change in electrophoretic mobility of a structure produced by increasing the temperature. Samples are electrophoresed in two dimensions, through an increasing temperature gradient in the first, and through an electric field that separates molecules according to size in the perpendicular direction. For example, analysis of interactions between the P4 and P6 domains of the self-splicing Group I RNA from Tetrahymena demonstrated that tertiary structural folding is driven predominantly by \(\Delta H\), with a smaller \(-T\Delta S\) contribution to \(\Delta G\).\(^{58}\)

Continuous mixing analysis has been used to study equilibria between strands, a duplex and a triplex. Absorbance changes, due to continuous variations in strand number in populations containing two- and three-stranded complexes, were used to determine stoichiometries. Relative concentrations of oligo(A) relative to oligo(U) were varied from 1:10 to 10:1. The data led to the interpretation that two duplexes disproportionate to produce an \([\text{oligo(A)}\cdot\text{oligo(U)}]\) duplex at A/U \(\approx 1:1\) and an \([\text{oligo(A)}\cdot\text{oligo(U)}\text{,}2]\) triplex when the ratio is ca. 1:2.\(^{32}\)
6 CONDITION-DEPENDENT STRUCTURAL TRANSITIONS

6.1 Cation Dependences

Nucleic acid structural transformations can be induced by changing the existing solution components, concentration, temperature, ligand binding and many other factors. Cation concentrations can strongly influence their stabilities by modulating melting rates and reaction–product equilibrium distributions. Atmospherically bound cations are relatively loosely bound to the anionic oxygens of the phosphodiester backbone [equilibrium dissociation constant ($K_d$) $\approx 10^3$ M$^{-1}$]. Duplex dissociation is accompanied by cation (counterion) release. Counterion condensation theory\(^{(29)}\) was developed to fit cation–nucleic acid binding isotherms (curves) measured using $\text{^{23}Na-NMR}$. Fits require that only about 90% of the phosphodiester backbone charge (due to anionic oxygens) be neutralized to achieve thermodynamic equilibration. Duplexes have a higher negative radial charge density than individual strands. Because cations help neutralize the additional charge density, duplexes become favored and stabilized as the salt concentration is increased. The trend of increased charge density continues in proceeding to triplexes and quadruplexes. The surrounding cations are accompanied by H$_2$O molecules that are packed more densely than bulk H$_2$O, held within a Donnan sphere as a result of osmotic pressure (and other effects produced by dissolved osmolytes).

The right-handed B-form duplex poly[d(CG)$_2$] is converted to the left-handed Z-form with a transformation midpoint at ca. 2.2 M NaCl using strands in the micromolar range.\(^{(30)}\) Placing bulky bromine atoms or methyl groups at the C8 atoms of guanines 8-bromoguanosine (br$_8$G) induces Z formation because the base swings about the glycosidic bond, relative to the sugar ring, from the B-form anti conformational isomer (conformer) to the syn structure. The B- to Z-DNA conversion also occurs upon adding 5 mM MgCl$_2$, but only if the Cs are methylated, poly[d(m$^5$CG)$_2$], illustrating a case of transformational induction mediated by two synergistic factors. The physiological MgCl$_2$ concentration is ca. 1–5 mM, but varies with organism and cell type. Cytidine methylation occurs naturally in many chromosomal domains in patterns that vary with cell-cycle phase and developmental stage dependent factors.\(^{(2,4,47)}\) Correlations suggest that Mg$^{2+}$ and m$^5$C may work to induce B to Z transitions in live cells under some circumstances.

The Z-form of RNA adopted by poly[r(CG)] is much more difficult to induce than Z-DNA. Z-RNA formation occurs in buffer at a transition midpoint of 6 M NaClO$_4$, a much more chaotropic salt than NaCl, and heating to ca. 40 $^\circ$C. A solution of 4 M MgCl$_2$ in buffered 10% ethanol also works. Like DNA, the presence of br$_8$G induces Z-RNA formation; unlike DNA, 5-bromocytidine (br$_8$C) inhibits Z-RNA production. Molecular mechanics modeling analysis suggests that the difference can be attributed to steric repulsion between the C5 bromine atom and the 2'-hydroxyl, which is missing in DNA.\(^{(66)}\)

Changing the type of cations and their concentrations and also the strand concentration(s) can profoundly affect the stability of quadruplex DNA. Guanine-tract-containing RNAs also readily form the quadruplex, e.g. a fragment from E. coli 5S RNA (Figure 13b, ca. nucleotide 80).\(^{(16)}\) Manipulating these factors can induce transitions from duplex to quadruplex and (under very specific circumstances) vice versa. Quadruplexes are stabilized by Group 1a monovalent cations in the order K$^+$ > Na$^+$ > Rb$^+$ > Li$^+$ and Cs$^+$ by binding in the center of the Gs, forming a cation spine down the central axis of the complex (Figure 10b). The distribution of products formed by two different quadruplex formation pathways, from two or four strands, can be varied by manipulating the total concentrations of strands, K$^+$ and Na$^+$. This phenomenon, the sodium–potassium switch, permits control over the predisposition to form alternative quadruplex structures from strand precursors by manipulating cation and strand concentrations.\(^{(17–21)}\) Re-equilibration involves competition for unpaired strands, the common source of reactants used in the two competing assembly processes. At low Na$^+$ or K$^+$ concentrations (<240 mM Na$^+$ or <65 mM K$^+$), the antiparallel quadruplex formed by annealing two hairpin side-by-side forms. At higher salt concentrations, the parallel four-stranded quadruplex forms. As the DNA concentration is increased, less K$^+$ is required to induce the parallel-stranded quadruplex, which is preferred over the two-stranded antiparallel structure.

WC duplex formation is usually preferred relative to quadruplex formation because the duplex association rate is typically much faster than that for quadruplexes, but not always. For example, at elevated strand and K$^+$ concentrations, [d(CGCG GCGG GCGG)]$_2$ quadruplex formation becomes preferred over the WC hairpin.\(^{(20)}\) Quadruplex assembly competes successfully with the hairpin formation pathway for strands.

When sufficient monovalent cation is present, divalent cations typically stabilize duplexes, triplexes and quadruplexes. Concentrated nucleic acid/divalent cation solutions are prone to forming aggregates containing large strand stoichiometries.\(^{(61)}\) Curiously, >20 mM Cd$^{2+}$ or Zn$^{2+}$ can dissociate examples of all three types of complex.\(^{(62)}\) For example, the quadruplex [d(CGCG GCGG GCGG)]$_2$ is dissociated with the following predispositions: Cd$^{2+}$ > Zn$^{2+}$ > Ca$^{2+}$ > Mg$^{2+}$. Much higher concentrations of some divalent cations (Cd$^{2+}$, Zn$^{2+}$) are also known to dissociate duplexes and triplexes. The sensitivity
of duplexes, triplexes and quadruplexes to dissociate at comparatively low divalent cation concentrations may support significant transformation events among different forms of condensed nucleic acids in genomic chromatin, packaged virus particles or other niches.

A duplex DNA fragment in supercoiled plasmid DNA was found to form two different types of H-DNA triplex, with and without added Mg$^{2+}$. A triplex stabilized by G$^\cdot$G$^\cdot$C base triplet forms when the sequences shown in Figure 8(a) and (b) contains 2 mM Mg$^{2+}$.(10) In contrast, an alternative C_H$^+$$\cdot$G$^\cdot$C-containing H-DNA triplex structure forms in the absence of Mg$^{2+}$.

B-form duplex DNA has between 15 and 20 surface-bound H$_2$O molecules per nucleotide.(63) In one structure, about 17 waters bind, five in the vicinity of each base pair, four associated with each phosphate and two bound to the sugar. All of the base pairs are associated with the same number of water molecules, water binding is approximately sequence independent. A spine of hydration can form in the minor groove of the crystal structures of AATT sequence-containing DNAs, reinforcing the B-form structure by participating in bidentate interactions with T$^\cdot$O$^2$ and A$^\cdot$N$^3$.(1,63) Energy studies suggest that these hydration interactions help stabilize the duplex. Osmotic pressure is a key energetic consideration; added osmolytes can dramatically affect the stabilities.

Certain repeating oligo(A$^\cdot$T) tract sequences can be placed in the proper position and appropriate phase with respect to the helix pitch, the length of one turn of the helix, to produce bent DNA.(64) Only properly phased sequences work because they ensure that subcontributions to the bend accumulate far enough to produce the fully realized change in net helix orientation. When the sequences are not properly phased, long-range bending does not occur.

This is a relatively extreme example of DNA structural microheterogeneity. Crystallography results demonstrated that there are sequence-specific differences in rotation between base pairs in B-form DNAs, lateral positioning of base pairs relative to the helix axis and propeller twisting of the two bases within a base pair with respect to each other, etc. (Figure 17a and b).(1,6,42) These specificities have been incorporated into rules that can be used to predict how sequence changes affect helical microstructures.

### 6.2 Ligand-induced Structural Transformations

Nucleic acids often undergo structural transformations when proteins bind. A vast canon of enzyme-catalyzed, sequence-specific covalent cleavages, modifications, ATP-requiring locomotion events, decoding and rearrangement reactions, etc., form the basis of modern molecular biology.(2,3,55) Protein structures must often adapt and mold to their ligand upon binding to accomplish these processes. Because the backbone of DNA is negatively charged, DNA-binding domains in proteins are typically composed of positively charged, often protonated, amino acids, arginine, lysine and histidine. Since the bases are prone to stacking interactions, the aromatic amino acids phenylalanine, tyrosine and tryptophan are also common in nucleic acid binding proteins. They function by stacking between base residues to form intercalative interaction in the [protein$\cdot$DNA (or RNA)] co-complex.

The protonated, polycationic polyamines spermine and spermidine resemble the electropositive amino acids, providing a small molecular model to help understand how analogous protein fragments bind, neutralize and stabilize DNA and RNA structures in vivo. Spermidine is required to crystallize tRNAs and in many nucleic acid and [nucleic acid$\cdot$protein] co-complex crystallization protocols.(1) It is thought to function by neutralizing the polyanion tRNAs and reducing intermolecular repulsions in the crystal. Both of these polyamines induce the B- to Z-DNA transition, at micromolar concentrations when m$^2$Cs are present – almost three orders of magnitude less than the Mg$^{2+}$ concentration required to do the same.

Specific DNA-binding elements in proteins mediate most known genetic control mechanisms. Two important duplex DNA-binding motifs, the helix–turn–helix and zinc finger, are very common in the DNA-interaction domains of repressor and transcription factor proteins.(55) Sequence-dependent differences in functional groups in the major and minor DNA grooves produce specific recognition sites, leading to protein-mediated recognition, specificity and regulation. Two DNA-binding proteins, e.g. transcription factors, often bind each other via two entwined $\alpha$-helices, one contributed by each protein, called a leucine zipper.

Protein binding is usually fairly specific for one base sequence, the consensus sequence. In some cases, however, a broad range of sequences is recognized. An extreme example of broad RNA recognition specificity occurs with phage T4 late transcript regA mRNAs, which display a broad range of viable consensus binding sequences.(65,66) This range was studied quantitatively by assessing the propensities of randomized RNAs to evolve through a series of regA protein-binding selection steps using a technique called systematic evolution of ligands by exponential enhancement (SELEX). This process involves a series of consecutive cycles of substeps: nitrocellulose filter binding, reverse transcription, cloning to complete each cycle and sequence determinations following each round to follow the process. Tetraloop structures formed by the RNA strongly inhibit their
reverse transcription, being so stable they essentially stop protein transit.

A general model has been developed to understand specificity in protein–DNA binding interactions. The researchers wanted to determine how repressor proteins specifically recognize their correct operator DNA and reject nonspecific DNAs. The findings highlight the subtlety of specific DNA recognition. Electropositive binding proteins all have an intrinsic propensity to bind any nucleic acid sequence by virtue of its polyanionic charge, the predominant externally recognizable property. The protein cannot bind too tightly or repression cannot be easily reversed; binding constants for repressor binding to specific DNAs are typically only about five-fold larger for the correct consensus sequence than for any sequence. All sequences are bound with comparable association rate constants \((k_a)\). Specificity is maintained by having incorrect sites dissociate much more readily (quickly) than correct sites, i.e. the dissociation rate constant \((k_d)\) is larger for correct than for incorrect sites. As a result, proteins stick to correct sites and are lost from incorrect sites. The high \(k_a\) ensures that the protein will rebind elsewhere, eventually sticking when the correct sequence is encountered.

Modular components, excised from their full molecular context for study, are being used to learn how they function in their more complicated niche. A few selected examples are described briefly below. In each of these cases, the nucleic acid structure interacts with a protein ligand that contributes significantly to the net energetics of the process.

The arginine fork motif mediates specificity in the HIV [tat protein-TAR RNA] binding interaction. In this model, an internal bulge and a nearby six-nucleotide loop mediate specific binding of the tat protein, leading to transcriptional activation. Upon arginine binding, the bulge changes conformation, and essential nucleotides for binding form a U-A-U base–triple interaction that stabilizes arginine hydrogen bonding to a nearby G and phosphates.

The HIV Rev peptide binds stem–loop IIB of the Rev Response Element RNA. The Rev peptide has an \(\alpha\)-helical segment that binds in the major groove of the RNA near a purine-rich internal loop, with several arginines making base-specific contacts, including a G-A base pair. NMR studies demonstrated that the phosphodiester backbone adjacent to a G-G base pair adopts an unusual structure that allows the peptide to access a widened major groove. The major groove of A-RNA is normally deep and too narrow to accommodate an \(\alpha\)-helix, thus requiring non-WC interactions to widen the groove.

The protein CBP2 binds RNA tertiary structure and is required for efficient splicing of a yeast mitochondrial Group I intron. CBP2 must wait for folding of the two RNA domains that make up the catalytic core before it can bind. Subsequently, association of the 5' domain of the RNA is stabilized by additional interactions with the protein. Thus, CBP2 functions primarily to capture otherwise transient RNA tertiary structures.

ACKNOWLEDGMENT

We thank Rebekah Gunn for obtaining copyright releases and Professor Dennis Brown for providing support. C.C.H. thanks his students, professional colleagues and mentors, Professors Jack Horowitz, Ignacio Tinoco, Jr and Paul Agris, for their contributions, insights and enthusiasm for this ‘‘good fight’’.

FURTHER READING

We have attempted to present an even-handed view of this vast field, but this account is limited. We included the following Further Reading to broaden the scope, yet minimize space. We have glossed over many important theoretical developments, biotechnological advances and medical applications of nucleic acids. Consult the cited articles for much more about the inner workings and uses of these fascinating molecules.

Our sentiments about nucleic acids track well with those of author Jim DeRogatis: “Like any history, this one is subjective. Another account of psychedelic rock [Jim’s subject] could be written emphasizing an entirely different set of artists (scientists in our case), and I would enjoy reading it. . . . My goal was to share my enthusiasm for music (nucleic acids studies) that I consider to be some of the finest that rock (biophysical chemistry) has produced”. [J. DeRogatis, Kaleidoscope Eyes, Citadel Press, Secaucus, NJ, 1996.]

Optical mapping is a system for the construction of ordered restriction maps from single deoxyribonucleic acid (DNA) molecules. DNA molecules bound to derivatized glass surfaces are cleaved with restriction enzymes and imaged by fluorescence microscopy. Cut sites are visualized as gaps between cleaved DNA fragments, which retain their original order. Optical mapping offers advantages over electrophoretic methods of restriction enzyme analysis, which require separate techniques for separating cleaved DNA fragments and determining fragment order. Furthermore, small amounts of DNA are required for optical mapping analysis. By determining the existence of these sequence-specific cut sites and the distances between them, a precise landmark map of the DNA sequence can be constructed. Prokaryote and eukaryote DNA can be mapped. Maps can be constructed from both cloned DNA and genomic DNA. Restriction maps can be constructed for whole genomes by overlapping maps derived from individual molecules. Such maps provide a useful scaffold for accurate alignment of sequence contigs generated by a shotgun sequencing approach and a means of comparing populations and strains.

1 INTRODUCTION

1.1 Principle

Optical mapping is a single molecule approach for the rapid construction of ordered restriction maps. It dispenses with electrophoretic approaches and uses fluorescence microscopy directly to image individual DNA molecules bound to specially derivatized glass surfaces which have been cleaved by restriction enzymes. Restriction enzymes are enzymes that recognize and then cleave DNA at a sequence specific site, usually a four, six or eight nucleotide motif. Different restriction enzymes recognize different motifs. A restriction map is a linear array of sites on DNA cleaved by one or more restriction enzymes showing the mass, in basepairs (bp), of the ordered fragments predicted from the digest.

Large DNA molecules, greater than 10 kilobases (kb) in size, are mounted on silanized glass surfaces. Fluid flows elongate the DNA molecules and electrostatic interactions hold the stretched DNA molecules on...
the surface. Molecules are digested with a restriction enzyme. Cleavage sites are visible as small gaps between DNA fragments, which retain their original order. DNA is stained with an intercalating dye, visualized by fluorescence microscopy and digital images are recorded. Fragments are sized by measuring integrated fluorescence intensity and ordered restriction maps of single molecules are constructed. A restriction map created from a single DNA molecule is limited in its accuracy by the resolution of the microscope, the imaging system, surface conditions and the biochemistries used. Statistical approaches are therefore used to construct finished maps from an ensemble of imperfect maps such as those derived from partially digested molecules. Consensus maps of cloned DNA are created using a Bayesian inference scheme. Maps of genomic DNA are contiged using Gentig software. The final maps are an average of many individual maps.

1.2 History

Optical mapping was first reported in 1992. In the original method, ensembles of yeast chromosomes fluorescently labeled with 4,6-diamidino-2-phenylindole dihydrochloride (DAPI) were elongated in a flow of molten agarose generated between a coverslip and a microscope slide. The DNA was fixed in an elongated state when the agarose gelled. Restriction enzymes were present in the molten agarose and the DNA was cut when magnesium ions diffused into the gel. As the DNA relaxed, the cut sites in individual molecules were resolved by imaging the receding cut ends by time-lapse video microscopy. Ordered restriction maps were constructed by measuring the relative fluorescence intensity and apparent molecular contour length of a number of DNA fragments, followed by averaging. Fragment sizes determined by optical mapping correlated with sizes obtained by pulsed field gel electrophoresis (PFGE) and were more informative since the fragment order was determined concurrently. The approach had other advantages over PFGE in that multiple copies of the same sequence are present on the same surface (Figure 1). Statistical approaches are used to construct finished maps from an ensemble of imperfect maps derived from individual molecules. Imperfect maps are generated as a consequence of partial digestion, desorption of small fragments, inaccurate sizing, etc. The final optical map is averaged from 20–40 single molecule maps. BAC maps can be contiged together by aligning restriction sites to cover large genomic regions and generate minimal tiling paths.

1.3 Optical Mapping of Cloned DNA

Mapping of cloned DNA offers advantages in that multiple copies of the same sequence are present on the same surface (Figure 1). Statistical approaches are used to construct finished maps from an ensemble of imperfect maps derived from individual molecules. Imperfect maps are generated as a consequence of partial digestion, desorption of small fragments, inaccurate sizing, etc. The final optical map is averaged from 20–40 single molecule maps. BAC maps can be contiged together by aligning restriction sites to cover large genomic regions and generate minimal tiling paths.

![Digital fluorescence micrograph of some typical BAC molecules.](image)

Figure 1: Digital fluorescence micrograph of some typical BAC molecules. This 100kb BAC, derived from the human Y chromosome, was digested with NdeI. Ordered restriction fragment sizes are 26.6, 3.5, 2.9, 29.1, 3.1, 2.3, 12.4, 6.2, 4.5, 5.7 and 3.5 kb.
Optical mapping of genomic DNA enables restriction maps of entire microbial genomes to be constructed.\(^{13,14}\) The substrate is large randomly sheared genomic DNA molecules 0.4–3.0 Mb (megabases) in size (Figure 2). The resulting maps generated using such a “shotgun optical mapping” strategy have many overlapping restriction sites permitting contig formation either by visual alignment\(^{14}\) or by “Gentig” software (described below).\(^{3,13}\) Library construction is obviated enabling mapping of organisms with AT-rich DNA, which is difficult to clone. Also, cloning artifacts are precluded, enabling more accurate maps to be generated. Such maps have proved invaluable as a scaffold for assembling of sequence contigs and as a means of sequence verification.\(^{16}\) Optical mapping also provides insight into the genomic structure of the organism, revealing the presence of large extrachromosomal elements, which can only be identified at the single molecule level.\(^{13}\)

2 METHODOLOGY

2.1 Cleaning of Glass Surfaces

Optical mapping surfaces must be cleaned thoroughly before use to ensure uniform derivatization and optical transparency. For safety and cleanliness a self-contained acid boiling system, built from pyrex glass and Teflon\(^{\text{TM}}\) tubing and assembled in a fume hood, works best. No vacuum grease is used to seal the joints. A sodium hydroxide scrubbing system neutralizes acid vapors. Coverslips are racked in custom-made Teflon\(^{\text{TM}}\) racks, which hold the coverslips snugly on three edges, and cleaned by boiling in concentrated nitric acid (HNO\(_3\)) for 24 h. The system is rinsed extensively with deionized dust-free water until the effluent attains pH 6. The cleaning procedure is repeated with concentrated hydrochloric acid (HCl) which hydrolyzes the glass surface, preparing it for subsequent derivatization. The racked coverslips are rinsed extensively and then sonicated in deionized water to remove residual acid which collects between the Teflon\(^{\text{TM}}\) parts in the racks. Residual water is then removed by sonicating the racks in distilled ethanol. The cleaned coverslips are stored at room temperature in the racks under distilled ethanol in polypropylene containers.

2.2 Derivatization of Glass Surfaces

Cleaned coverslips are derivatized in slotted Teflon\(^{\text{TM}}\) racks which hold the coverslips by one edge. Surfaces are derivatized for 48 h at room temperature on a rotary shaker in 3-aminopropyltriethoxysilane (APTES), between 7 and 28 \(\mu\)M, in ethanol.\(^{10,12,17}\) Macroscopic derivatization parameters such as silane concentration and duration of silane treatment alter the surface charge density which plays a critical role in surface-based optical mapping. The surfaces are checked for optimal performance by estimating the hydrophobicity by measuring the contact angle and assaying the degree of DNA stretching and fragment retention. Derivatized surfaces can be stored in treatment solution for a few weeks. Surfaces can also be derivatized with 3-aminopropyldiethoxymethylsilane (APDEMS)\(^{14}\) or 3-(triethoxysilylpropyl)trimethylammonium chloride (TESP).\(^{11}\)

2.3 Preparation of DNA Molecules

Circular BAC and cosmid molecules are prepared by standard alkaline lysis protocols\(^{18}\) or commercial plasmid preparation columns. Molecules are linearized with \(\lambda\)-terminase prior to surface mounting.\(^{10}\) \(\lambda\)-Terminase is an endonuclease which cleaves at the \(\lambda\) cos site. Occasionally, circular DNA is linearized by restriction digest utilizing a Not I site in the polylinker of the cloning vector when no internal Not I sites are present in the insert.\(^{10}\)

Increasing the size of measurable genomic DNA molecules decreases the number required for mapping a complete genome.\(^{19}\) To minimize shearing, approaches similar to those used to prepare large DNA molecules for PFGE are used.\(^{6,7}\) Genomic DNA is isolated from cells embedded in low melting point agarose gel inserts which are treated with proteinase K and detergents. Essentially intact DNA is isolated following melting of
the agarose. Physical manipulations such as pipetting can shear large DNA molecules so these are kept to a minimum, and where necessary, wide bore pipetting devices with a slow delivery rate are used. Molecules over 2 Mb can be mounted. Shearing of genomic DNA can also be minimized by condensation of DNA molecules with spermine, a polyamine which collapses DNA coils embedded within agarose. The subsequently molten agarose can be subjected to manipulations as severe as vortexing which would ordinarily shear DNA. The DNA particles are decondensed by washing of gel inserts in spermine-free buffer supplemented with NaCl.

2.4 Mounting of DNA Molecules on Surfaces

DNA molecules exhibit rod-like behavior below ~3 kb, and show evidence of random coil behavior above 3 kb. DNA molecules interact with derivatized surfaces via electrostatic interactions between the anionic DNA and cationic surface. Molecules attach to the surface at one end and then stretch out in the fluid flow. Efficient binding and analysis of molecules relies on a balance between flow and electrostatic forces. High-fluid flow combined with a high surface charge density causes overstretching of the molecules, leading to breakage of molecules during and after mounting. Low-fluid flow combined with a high-surface charge density causes understretching of the molecules, leading to coils of DNA deposited on the surface.

By carefully controlling surface conditions, large DNA molecules can be mounted without significant breakage. Too high a surface charge density yields poorly stretched, or stretched intact DNA molecules which fail to digest. This may be due to occlusion of enzyme binding sites caused by severe adsorption of the molecule to the surface. Alternatively, cleavage may occur, but insufficient relaxation occurs to produce an observable gap. Indeed, both mechanisms may apply. Insufficient charge density leads to desorption of DNA fragments smaller than about 1 kb from the charged surface following digestion. The larger the DNA molecules, the lower the required surface charge density. Genomic DNA requires lower charge density than BACs, which require lower charge density than cosmids.

Molecules mounted by the peeling method require lower surface charge density than those mounted by the spotting method (see below). Because optical mapping uses fluorescence intensity measurements for mass determination, complete elongation of the DNA molecules is not required for mapping, but it does facilitate the data analysis and provides more mapping information because more cutting sites are resolved. DNA is mounted by either “peeling” or “spotting” protocols.

In the peeling protocol, a few microliters of DNA solution are pipetted onto a microscope slide and a derivatized coverslip is carefully placed on top of the sample to spread out the drop. The coverslip is removed carefully with forceps (“peeled”) and rinsed in Tris–ethylenediaminetetraacetic acid (TE) buffer. The amount of DNA mounted on a surface is titrated on a surface-by-surface basis to give optimum numbers of DNA molecules per microscope field of view. A high density of mounted molecules gives more information but also leads to crossed molecules and an inability to resolve groups of fragments from different molecules. DNA molecules have also been mounted by motor-driven movement of a meniscus held at a 45° angle between a coverslip and a derivatized slide. A procedure for binding DNA molecules at a gel/solution interface has also been developed.

Gridding of multiple samples on a single surface and processing them in parallel is a strategy employed in hybridization-based approaches and also in optical mapping. The spotting protocol permits multiple DNA samples to be mounted on a single surface. This enables

Figure 3 Digital fluorescence micrographs of gridded spots containing fluid fixed molecules. Droplets of *λ*-bacteriophage DNA onto APTES treated glass surfaces, dried and stained. USA*, 95, 8046–8051 with permission. Copyright (1998) National Academy of Sciences, USA.)
digested and analyzed in parallel. Droplets of DNA samples are “spotted” in 10 x 10 grids using a modified commercially available Biomek laboratory automation robot (Figure 3). The fluid flows generated within drying droplets bring the DNA molecules closer to the surface where they bind in an elongated conformation. The robot is able to deposit one sample approximately every 10 s. Spoting tools include glass capillaries, pipette tips or solid tips which deposit volumes of 10–20 nL using several programs which alter spotting patterns. Such automated high-density deposition techniques make optical mapping an ideal high throughput system for genomic analysis of clones.

2.5 Restriction Digestion of DNA
Molecules on Surfaces

The optimal restriction enzyme digestion conditions, in terms of digestion time and enzyme concentration, depend on the enzyme being used and the surface characteristics. Cutting efficiencies are routinely greater than 80%. Efficient cutting of genomic DNA is obligatory for confident contig formation by Gentig software (described below). Typically, 5–20 units of enzyme in 50–20 mL of buffer, are pipetted onto the surface. Digestion is carried out at room temperature for 10 min to 2 h in a humidified closed chamber. The digestion reaction is terminated by aspirating off the enzyme and then distilled water. DNA molecules are stained with oxazole yellow homodimer (YOYO-1) in 20% β-mercaptoethanol. YOYO-1 is a fluorescent dye which bis-intercalates between the DNA bases at one molecule (two fluorophores) per four bps. YOYO-1 solution is pipetted onto a microscope slide and the sample coverslip is placed on top of it. The edges of the coverslip are sealed onto the slide with transparent nail polish. Alternatively the coverslip is sealed onto the slide with transparent nail polish. Human DNA is roughly 50% GC but the content of microorganisms varies greatly. For example, Plasmodium falciparum DNA is only 18% GC. NheI and BamHI were chosen to map this organism since they recognize sequences with a GC bias (GCTAGC and GGATCC) and would prevent too frequent cutting. Assuming a random distribution of nucleotides across the genome, the predicted cutting frequency with these enzymes would be every 91 kb. The average sizes of the fragments generated by optical mapping of the whole genome were 24 kb and 32 kb, respectively. Deinococcus radiodurans DNA is 68% GC, predicting an NheI cutting frequency of 3 kb. When this organism was mapped with NheI, the average size of the fragments was 29 kb. This demonstrates that the GC/AT content of these organisms is not randomly distributed and each genome must be evaluated empirically on an organism by organism basis. Consequently, before optical mapping begins, a digest is performed in solution with a variety of candidate enzymes and a distribution of fragment sizes is determined by PFGE.

Enzymes that work in a NaCl-containing buffer (50–150 mM) are required since salt-free buffer does not permit relaxation of the DNA on the surface following digestion. Higher salt concentrations cause more DNA relaxation and less retention of small fragments. The restriction enzyme buffer needs to be compatible with the surface charge density. Surfaces with high charge density are used with high salt buffers and surfaces with low charge density are used with low salt buffers. Buffers containing potassium salts in place of NaCl alter the integrity of the surface-mounted DNA, in a presently unknown manner, and therefore enzymes that work in these buffers cannot be used. Consequently, not all restriction enzymes can be used for optical mapping.

2.7 Sizing of DNA Molecules

Fluorescence intensity measurements are used for DNA fragment mass determination. An internal standard of known length is used to size fragments accurately. In the case of cloned DNA this can be the vector which has NoI restriction sites in the polylinker at either end. The pBAC108L vector, for example, gives a 6.9-kb sizing standard. Circular molecules can therefore be mounted on surfaces and sized in a circular form. In the case of genomic DNA, λ-bacteriophage DNA (48.5 kb) or cosmid DNA (about 45 kb) can be co-mounted with the sample (Figure 2). Cutting efficiency can also be estimated if the co-mounted standard possesses a restriction site for the enzyme used for mapping.

2.8 Instrumentation

The optical mapping workstation (Figure 4) is built around a Zeiss™ 135 Axiovert inverted microscope.
Figure 4 Optical mapping workstation. The schematic illustration shows how the microscope, silicon intensified target (SIT) video camera, cooled CCD camera, LUDL™ controller and Sun workstation are integrated.

equipped for epifluorescence, with several different objectives (40, 63 and 100× Zeiss™ plan-neofluor oil immersion) allowing for imaging of biomolecules of a wide range of sizes. The 100× objective is most commonly used, whereas the 63× objective is used for clones larger than 200 kb. Filter packs allow for imaging of biomolecules labeled with fluorescent dyes of different spectral properties. The microscope is equipped with a Dage™SIT 68GL low light-level video camera and accompanying monitor for automatic and manual focusing, and a Princeton Instruments cooled CCD camera (1317 × 1035 pixels, KAF 1400 chip, 12-bit digitization) for acquiring high-resolution digital images. Automatic features such as movement of the microscope stage (0.1-µm resolution), image collection, light shutter operation and video autofocusing are controlled by a LUDL™ Electronics box, which contains a LUDL™ Electronics MAC 2000 interface bus, housing all interface cards (PSSYST 200, MCMSE 500, MDMSP 503, AFCMS 801, FWSC 800, and RS232INT 400). The LUDL™ MAC 2000 is interfaced via a RS232 serial connection to a Sun Microsystems™ SPARC 20 dual processor computer workstation. The CCD camera is also interfaced, via a pentium-based microcomputer controller and a distributed network, to the Sun workstation. The Sun workstation is part of a distributed network on which interactive and automatic image processing is performed. Software for control of the above peripherals is written in the C programming language. The optical mapping workstation is mounted on a floating optical table.

2.9 Microscope Automation Software and Collection of Images

DNA molecules are imaged using optical map maker (OMM) software, operated through a collection of user-friendly interfaces, and the image collection process can be followed on the Sun workstation monitor.
Digital images can be acquired by the workstation at the set by the operator so that the pixel value on any part by the CCD camera and the final imaging time is then diameter can also be varied. A sample image is collected imaging time, sample grid position and size, and spot are incorporated. Image acquisition parameters such as and image collection. Manual and fully automatic modes are incorporated. Image acquisition parameters such as imaging time, sample grid position and size, and spot diameter can also be varied. A sample image is collected by the CCD camera and the final imaging time is then set by the operator so that the pixel value on any part of the molecules is below saturation (4095 gray levels). Digital images can be acquired by the workstation at the rate of 4 min^{-1} (using 5 s imaging time). The development and implementation of automated microscope operations has enabled operator-free imaging of optical mapping surfaces. An operator can enter the coordinates of a series of gridded spots and images are subsequently collected and tiled together automatically, only from the areas on the surface where DNA has been spotted. As part of a developmental path for large clone mapping with automatic image collection, the program “Mark and Collect” has been developed. This software saves the operators time spent waiting for images to be collected and transferred to the file system, which normally takes about 10 s per image. Microscope fields of interest are selected by the operator and the coordinates stored. When enough areas of the optical mapping surface have been identified the program subsequently moves the stage and collects the images. The image acquisition output is linked to the automatic map-making routines, so that after the images have been acquired and stored on hard disk arrays they can be either directly submitted for automatic image processing and extraction of restriction map data or saved for later processing. The OMM system can run on a network of other workstations. Access to all aspects of the OMM data and processing is made through one shared directory hierarchy. This file system structure and the accompanying software libraries provide uniform controlled access to all collection and processing activities and data. Several specially designed “viewers” permit the user to follow the different steps of the image analysis visually, so that convenient assessment and troubleshooting can be performed. A distributed processing system allows all the available computational resources on the network to be shared.

2.10 Correction of Images

The CCD camera produces images composed of 1317 × 1035 pixels of 12 bits each which are read out and stored as an array of unsigned 16-bit values. The intensity value for a pixel at no light is the dark value, and an image taken with the microscope shutter closed is a dark image. This dark image, which represents the electronic noise in the CCD chip, varies from camera to camera and with the parameters used for taking the image (exposure time, etc.). The first correction made to an optical mapping image is to subtract the corresponding dark image. The second correction, flatfield correction, is carried out to adjust for differences in the amount of light registered by a particular pixel that are not due to the difference in distribution of dye in the sample. Such variations can be due to nonuniformity of the light source, differences in the light path (smudges on optical components, etc.), and possibly other factors in the CCD and readout electronics. The correction involves dividing each pixel value in the image by the corresponding pixel value in a bright image, an image of a thin, in-focus, and uniformly fluorescent sample. Since the only fluorescence of interest is that emanating from dye bound to DNA molecules, other sources of fluorescence are considered background and the subtraction of this background contribution is the last correction made. Based on the assumption that the major source of background is unbound dye on the surface and that this does not vary rapidly, the background value for each pixel can be estimated. First, the median pixel values for pixels on concentric circles around the pixel in question are found. Then, a median of medians is taken, a median image calculated and a Gaussian smoothing operation applied to give the final background image. This image is subtracted from the flatfield corrected image.

2.11 Analysis of Images

The purpose of the analysis of optical mapping images is to find the cognate fragments derived from a single DNA molecule, and for each fragment calculate a signal representing the intensity in the image along the length of the molecule. DNA molecules are found by looking for long thin bright objects which have a dominant direction. In the first phase, an algorithm identifies these isolated regions in the image, using both the fluorescence intensity and local directionality properties at each pixel, where each region contains the fragments of a parental molecule not overlapping with other molecules. This is done by first applying a ridge filter to the input corrected image which produces 16 new images. Each image corresponds to one of 16 different directions and the value of a pixel in one of these images represents a calculation of the degree to which the pixel appears to lie on a ridge in the particular direction. An image is then constructed which contains, at each pixel, the highest of the 16 values for that pixel. A threshold value is picked so that the peak on the histogram for an area containing the segment to be measured is the midpoint between the threshold value and the lowest background value. A threshold is calculated for the new image and objects are identified as contiguous collections of pixels whose values exceed the threshold. At this point the objects (collections of pixels
with high numerical values) consist of pixels which are on ridges in some of the 16 directions, but since all 16 directions are included, and since the ridge filter tends to swell up in regions which have no predominant direction (e.g. at the ends of molecules), this image has a tendency to merge molecules which happen to be close to each other. To separate these molecules, the ridge filtering process is repeated for nine, then five, and finally three directions so that, in the final image, the objects consist of pixels lying along a ridge in one of three directions. This process has been shown to find and separate DNA molecules.

In the second phase, a path down the center of the molecule (the “backbone”) is computed using Dijkstra’s “all paths least cost” algorithm. A pixel in the middle of the molecule is chosen and the algorithm is applied to find the lowest cost path (traversing the molecule one step at a time from a pixel to one of its eight neighboring pixels) from the first pixel to each other pixel in the object. The cost of a path is the sum of the costs of the individual steps from pixel to pixel, and the cost function applied to each step favors moving to a pixel which is bright enough to be in the center of the molecule, but does not favor brighter pixels so strongly that the path wanders all over the middle of the molecule looking for the very brightest pixels despite the extra length. The paths from the first pixel to all boundary pixels are evaluated to identify an end-point pixel and the process is repeated using the end-point pixel instead of the first pixel. This finds the other end-point pixel and the path to it is the backbone. A smooth intensity signal along the backbone is then computed; for each position along the backbone, the intensity is calculated by summing the intensities for a set of pixels which are close to the backbone and lying along a line orthogonal to the backbone at that position. This intensity signal is then used to determine potential cut sites and estimated masses of all the potential fragments in that molecule. The estimated fragment mass data is normalized, and then, together with the information about the order of the fragments, collected for statistical analysis by the map-making program.

Images of single digested DNA molecules are taken using “GenCol”, a semiautomated image collection software which allows storage and seamless tiling of consecutive CCD images, covering the entire length of long genomic DNA molecules which span multiple microscope fields and is necessary for imaging of extraordinarily long DNA molecules.

The program “visionade” is an interactive graphical editing tool that allows a user to process a group of optical mapping images quickly, identifying fragments and molecules in the images with a few point-and-click actions. In the optical mapping system this step is done after a group of images has been collected and automatically flattened. Visionade is run on a group of images that contain molecules that are processed together to create a restriction map; e.g. a set of overlapping images containing a long genomic molecule and many copies of a smaller standard molecule which are used to size the fragments of the genomic molecule (see below). The user brings up an image, adjusts the color mapping to make the fragments clear, uses a threshold slider in the interface to color the fragments, clicks on the fragments to identify and number them, and then clicks again to group the current set of fragments into a molecule. The outputs of visionade are mask images locating the fragments and molecules. These outputs are combined with the flattened images to measure the sizes of the fragments in the molecules and this data is the input to the statistical analysis program “lcluster” (see below) which is a novel computational approach to map construction from optical data and finds the consensus map.

2.12 Map Construction Using Cloned DNA

The map making program “lcluster” gathers all of the per-molecule computations from all images and operates on them together. Here, the complete restriction map is computed by testing a set of plausible hypotheses about the restriction cleavage sites and choosing the most likely hypothesis supporting the previously accumulated data. The program starts by filtering out unsuitable molecules based on several criteria. (1) A molecule must have a total length in pixels between a specified minimum and maximum. (2) A molecule must not be within 10 pixels of the image boundary. (3) The maximum angle of curvature over the entire length must be below a specified angle (usually 30°). (4) The total intensity of the molecule due to pixels outside a specified distance from the backbone must be less than a specified threshold. These criteria tend to exclude most partial and overlapping molecules. Bayesian inference techniques enable the construction of maps from noisy data. For example, the map construction algorithms can produce maps from a population of partially digested clone molecules having a digestion rate as low as 15%. Bayesian estimation is used to determine the optimum way of accounting for each of the fragments in the filtered data set. A hypothetical model of the map is formulated, which specifies the following parameters: cut locations, the variance of cut site measurements, the cutting efficiency and the sample purity. Suitable probability distributions are applied to each of the parameters in the model. The cut locations follow a Gaussian distribution, false cuts are assumed to be uniformly distributed over the length of the molecule, the number of false cuts follow a Poisson distribution, and the cutting frequency is a simple function of the number of cuts. The object of the analysis is to find the maximum-probability model of the map given the data. The program
considers about 8000 models for each model size, i.e. maps of 2, 3, 4... fragments, and picks the 32 best models of each size, whose parameters are then optimized locally to converge to the nearest maximum in probability space. The best model of any size is accepted as the solution map if its probability density is significantly better than that of any other model.

2.13 Map Construction Using Genomic DNA

Whole genome optical maps are constructed by mapping large randomly sheared genomic DNA molecules. Overlapping maps are contiged by aligning restriction sites. Map contigs can be laboriously assembled manually over a course of weeks, or within minutes using “Gentig” software which automatically assembles map contigs and a consensus map from optical mapping data. Gentig uses a greedy algorithm with limited backtrack to find an almost optimal scoring set of map contigs, while constraining the false positive error rate below a negligible value. This approach ensures that the computed contigs are largely correct, although it fails to minimize the number of contigs. On the other hand, Gentig avoids the high computational complexity that would be incurred in attempting to find the optimal placement, a problem shown to be computationally infeasible in the most general setting. Molecular length and digestion efficiency control fragment alignment and are well-modeled by prior probabilistic (Bayesian) analysis. The Bayesian approach requires careful choice of parameters and a known prior statistical distribution of error sources. The standard deviation, digestion rate, false cut rate and false match probability can be altered to change the number of molecules that Gentig contigs together. The consensus map computed by Gentig is free of errors due to partial digestion, sizing error and false cuts.

The scoring function is computed from a Bayesian probability density estimating the probability that the two distinct component maps could have been derived from the proposed placement while subject to various data errors. The data errors which are modeled include sizing errors, missing cut sites, and false “optical” cut sites. First the most likely placement is hypothesized, then the probability density is computed for the mismatch errors in the component maps given the hypothesized placement and the error model. The second step is similar to the Bayesian probability density computation; one difference is that simplifying assumptions are made to improve computational efficiency. In particular, the hypothesized placement is computed by averaging of the contigged fragment sizes, rather than a true Bayesian probability density maximization with fragment sizes as parameters. Furthermore, good estimates of the error model parameters are assumed to be known a priori, but further improved by a re-estimation from the data using a limited number of iterations of a true Bayesian probability density maximization. The best offset and alignment between a pair of maps is finally computed by an efficient dynamic programming algorithm, thus avoiding a potentially exponential complexity.

2.14 Visualization of Map Data

Whole genome maps composed of many restriction sites and deep contigs are viewed with “ConVEx” (Contig visualization and exploration tool), which is a multiscale zoomable interface for cognition of large high-resolution contigged restriction maps. Users can examine the consensus maps together with the raw uncorrected data. Multiple representation of the graphical objects is presented in a scale-dependent manner and a powerful “lens” mechanism analyzes the underlying sequence data, enabling real time browsing of very large reference maps. The lens mechanism is augmented with a programming language (S-Lang language) allowing the user to create their own customized lenses. Such a lens (or a portfolio of lenses) provides a powerful tool for a user to examine the vast amount of data quickly stopping only infrequently to note a pattern, a point of interest or some editing of the data. Lenses facilitate examination of the global structure of the contig and provide annotation and editing mechanisms, allowing users to communicate interesting features such as STS (sequence tagged site) markers, even sequence reads.

3 OPTICAL MAPPING TO CHARACTERIZE GENOMES

3.1 Optical Mapping for Sequence Assembly and Verification

A prerequisite for characterizing and sequencing complex genomes is the availability of high-resolution maps of cloned DNA molecules. Optical maps support whole genome sequencing in two ways. First, optical maps are used to generate minimal tiling paths of large insert clones. Overlapping clones are contiged together by alignment of restriction sites (Figure 5). A minimal tiling path of clones is then chosen to minimize redundant sequencing. Second, optical maps of cloned or genomic DNA are extremely valuable to assist and ultimately confirm assembly of sequence generated by a shotgun approach (Figure 6).

A shotgun strategy has been employed to sequence the genomes of a number of microorganisms completely and sequencing of the human genome is an ongoing endeavor. DNA can only be sequenced in small portions
of about 500 bp. Shotgun sequencing essentially involves random fragmentation of the target DNA sequence, which can be an entire microbial genome or in the case of larger metazoan genomes a large insert clone such as a BAC. The resulting small fragments are cloned and sequenced. The assembly of sequence into contigs is accomplished using a number of software packages that read raw sequence from traces, search for homologous sequence to construct contigs, and allow significant editing of intermediate results. The entire target is redundantly sequenced to ensure maximal coverage and sequence accuracy. Nevertheless, some gaps still remain, often due to under representation in the library.

Optical maps can be used as a scaffold for accurate alignment of sequence contigs. A restriction map is created for each sequence contig in silico and optimally aligned with the optical map. Optical maps can also characterize gaps in terms of breadth and location and may facilitate closure techniques such as long-range PCR.

### 3.2 Very High-resolution Optical Mapping

The information content of a multiple restriction enzyme map is greater than the sum of its parts. Smaller sequence contigs can be placed on a multienzyme map. Multienzyme maps are generated by constructing single enzyme maps and then, by a series of double digestions, or use of available sequence information, these maps are combined into one dense construct. Optical maps of BACs digested with seven different enzymes have been overlaid to create a very high-resolution map with average fragment size 1.2 kb. Although this gives a very high density of markers, this resolution is still insufficient to anchor single sequence reads or genes.

Optical maps of genomic DNA have been linked using available sequence information. If a sequence contig contains restriction sites for two or more of the enzymes used to make the optical map, this contig can act as a linkage point to orient and align single enzyme optical maps. Rare cutter maps can be linked to existing frequent cutter maps by digesting the DNA into large fragments in a test tube with the rare cutter and then mounting these fragments on the optical mapping surface and mapping with the frequent cutter. The resulting maps are contiged against a consensus map using just the frequent cutter. Blunt ended, abutting contigs indicate...
the rare cutter sites. A scheme for aligning optical maps using Southern blotting has also been employed.\textsuperscript{(13–15,17)}

### 3.3 Identification of Repeated Regions

In the absence of restriction maps, repeated regions can confound sequence assembly efforts. The number of repeats and their orientation is often difficult to determine using sequence assembly software. Clones thought to contain repeats can be optically mapped using a restriction enzyme which cuts within the repeat, enabling the number of repeats and their organization to be revealed.\textsuperscript{(36)}

### 3.4 Identification of Genic Regions

Identifying coding sequences within mammalian genomes has proven both technically challenging and time-consuming, primarily because only small regions are transcribed; in the case of the complex human genome, 0.06\%. The figure drops to 0.007\% if purely exonic regions are considered.\textsuperscript{(37)} Optical mapping can be used to screen for genes in mammalian genomes.\textsuperscript{(17)} Expressed mammalian genes are characterized by a CG motif (CpG islands) which normally occurs at a low frequency in noncoding regions. CpG islands constitute a distinctive fraction of the genome because, unlike bulk DNA, they are nonmethylated and contain the dinucleotide CpG at its expected frequency. The average length of CpG islands is 1 kb and the haploid human genome is estimated to contain about 45,000 islands.\textsuperscript{(38)} All human housekeeping genes and 40\% of tissue-restricted genes are associated with CpG islands.\textsuperscript{(39)} In total, only 57\% of human genes have CpG islands, so unfortunately not all genes can be identified by CpG islands. Putative genes can be identified by optical mapping with enzymes which all have CpG in their recognition sequences such as NotI or EagI. However, CpG islands may not be of such value in locating genes in microbial genomes since these often possess strikingly different A + T and G + C content compared to human DNA.

### 3.5 Optical Mapping for Population-based Genomic Studies

If high-resolution maps can be rapidly generated, microbial populations can be analyzed at the whole genome level. Whole genome maps from related strains can be aligned and differences in the maps can show regions where the genomes differ. With the sequence of one strain in hand, maps generated from the unsequenced strain can be compared to identify regions unique to the other strain which could be targeted for sequencing.

---

### 4 COMPARISON WITH OTHER PHYSICAL MAPPING APPROACHES

#### 4.1 Gel Electrophoresis

The invention of PFGE in 1984\textsuperscript{(7)} enabled large DNA molecules to be separated based on their size, and opened the door to physical mapping of whole chromosomes and genomes. Large DNA molecules digested with rare cutter restriction enzymes could be separated, generating a fingerprint, but determination of fragment order was still dependent on Southern blotting, generation of probes and hybridization of filters. Optical mapping, on the other hand, provides unambiguous fragment order without further manipulations. Fragments can be sized more accurately by optical mapping versus PFGE. Sizing accuracy for restriction fragments generated from BACs is comparable if not superior to conventional and PFGE.\textsuperscript{(10,40)} Physical maps prepared by gel electrophoresis often fail to disambiguate repeats. Since optical mapping characterizes complex genomic regions at the level of single molecules, repeat complexities are discerned using restriction enzymes that cut once within a single repeating unit.

With a few notable exceptions, which include an eight-enzyme map of the *Escherichia coli* K12 genome\textsuperscript{(41)} and physical maps of the *Saccharomyces cerevisiae* genome,\textsuperscript{(42,43)} very few whole genome restriction maps have been constructed using electrophoretic approaches. High-resolution whole genome maps can be rapidly prepared by optical mapping. *Deinococcus radiodurans* and *Plasmodium falciparum* have been mapped and the fidelity of the maps was confirmed by sequencing of these genomes.\textsuperscript{(13,14,16,44)} Microgram quantities of DNA are required to analyze DNA by electrophoresis. Since optical mapping analyzes DNA at the single molecule level, small amounts of starting material are required. This enables mapping of microorganisms, such as parasites, which are problematic to culture. For example, an optical map of the whole 30-mb *P. falciparum* genome was prepared using no more than 2 ng of genomic DNA.

Electrophoretic approaches are not amenable to full automation to include sample preparation and analysis. Gridding of samples on a single surface and development of object recognition via computer, “machine vision”, has made optical mapping of cloned DNA a semi-automated process with the expectation that this type of development path can be extended to mapping of genomic DNA.

#### 4.2 Fluorescent In Situ Hybridization

Fluorescent in situ hybridization (FISH) has emerged as a powerful approach for gene and chromosome level analyses in clinical cytogenetics.\textsuperscript{(45,46)} FISH can be performed on metaphase chromosome spreads, interphase
nuclei\(^{47,48}\) and decondensed “halo” DNA.\(^{49}\) FISH is suitable for visualization of genetic aberrations affecting a few specific loci for which probes are available. However, its dependence on prior knowledge of genomic sequence makes it unsuitable for screening unknown genetic aberrations. FISH probes typically span 40–200 kb of genomic DNA.\(^{50}\) Aberrations smaller than 10 kb cannot be reliably detected. Interphase FISH cannot estimate distances between hybridization markers greater than 100 kb.\(^{51}\) Whole chromosome painting, multiluor FISH\(^{46,52}\) and spectral karyotyping (SKY)\(^{53}\) have enabled simultaneous visualization of up to 27 combinatorially labeled probes and this approach has revealed complex chromosome rearrangements not evident by conventional means.\(^{52}\) Development of fiber FISH,\(^{54,55}\) “where the hybridization template consists of highly deproteinized chromatin aggregated together to form multistranded DNA fibers, has enabled probes as small as 200 bp to be used to map exonic regions on cosmid clones.\(^{56}\) Such approaches could potentially be used to estimate numbers of duplicated expressed sequence tags (ESTs), or STTs examine chromosomal breakpoints in genomic DNA, or generate minimal tiling paths of clones.\(^{54,57}\) Restriction fragments have also been used as fiber FISH probes to generate rudimentary restriction maps of large insert clones.\(^{58}\) Short padlock FISH probes\(^{59}\) can be amplified at the site of hybridization by a rolling-circle mechanism\(^{60}\) and can be used to detect mutations.

Related approaches such as comparative genomic hybridization (CGH), which is a two-color hybridization of differentially labeled test and reference DNAs to normal human metaphase spreads\(^{61}\) or DNA fibers,\(^{62}\) and primed in situ labeling (PRINS), which is chromosome labeling performed by annealing of specific oligonucleotide primers followed by primer elongation by a Taq polymerase in the presence of labeled nucleotides,\(^{63}\) are used predominantly for studying gene copy number aberrations in tumors and are limited to gross chromosomal changes such as deletions, translocations and amplifications.

In situ hybridization-based approaches and optical mapping are similar in requiring surface mounting of large intact DNA molecules. Extended DNA molecules are mounted for fiber FISH analysis by “molecular combing”, whereby molecules attach at one end of the derivatized surface and are extended and aligned by a receding meniscus.\(^{64,65}\) Limitations of these other approaches include low throughput, DNA fragmentation which prevents subsequent or simultaneous multimethod analyses, and difficulties in automation. These molecular approaches generally yield low resolution maps and were developed primarily for characterization of single loci, not entire genomes.\(^{66,67}\)

### 4.3 Hybridization-based Microarrays

DNA probes can be gridded onto charged membrane surfaces\(^{26–29}\) and modification of technologies from the photolithography and semiconductor industries enable oligonucleotide probes to be gridded at extremely high density creating microarrays on “biochips”.\(^{68,69}\) DNA samples labeled with fluorescent tags hybridize to homologous probes and the fluorescence intensity for each segment measured. Biochips are used to detect mutations, quantitate nucleic acids, and create gene expression profiles from different cell populations.\(^{70–72}\) Although such hybridization-based approaches and optical mapping are both performed on surfaces and are amenable to high throughput by gridding of samples, this is where the similarities end. There is no underlying biochemical process in hybridization to probes. Biochips require prior knowledge of sequence whereas optical mapping can characterize unknown sequence. The hybridization on biochips is to short oligonucleotide DNA sequences\(^{68,69}\) and the means by which biochips cover large genomic regions is by gridding of hundreds of thousands of probes on a single chip.\(^{73}\) The number of samples that can be gridded on an optical mapping surface is limited first by the length of the molecules, which in the case of BACs can be in the order of microns, and second by the area on the surface which is required to generate sufficient fluid flow to stretch DNA molecules in the sample.

### 4.4 Other Single Molecule Approaches

Other single DNA molecule approaches have included visualization of single DNA molecules by fluorescence microscopy in solution,\(^{74–76}\) and during gel electrophoresis,\(^{75,77–79}\) restriction mapping of cosmid clones by atomic force microscopy of restriction enzymes bound to DNA,\(^{80}\) visualization of DNA by scanning tunneling microscopy,\(^{81}\) scanning force microscopy of circular DNA and DNA bending in transcription complexes,\(^{82,83}\) direct mechanical measurement of the elasticity\(^{84}\) and supercoiling of single DNA molecules using magnetic beads.\(^{85,86}\) These approaches have been useful in characterizing structural and functional properties of single DNA molecules but have not found application in generating physical maps of genomes since applicability to automation and throughput are obstacles.

### 5 RECENT IMPROVEMENTS AND FUTURE DEVELOPMENTS

In order to map arbitrary sequences and gene locations, RecA-assisted restriction endonuclease (RARE)
digestion has been combined with optical mapping.\textsuperscript{(87)} In this approach, DNA samples containing EcoRI sites are embedded in agarose inserts. RecA protein/oligonucleotide complexes bind to specific targets which contain EcoRI sites spanned by additional specific sequence of interest. Binding of the complex prevents the action of EcoRI methylase activity, which is used to methylate EcoRI sites which lack the specific oligonucleotide sequence. After RecA protein removal, the protected sites become the only non-methylated sites and are thus uniquely cleavable with EcoRI. The molecules are then mounted and mapped optically.

Restriction digests on surfaces are not the only biochemical reactions that can be assayed at the single molecule level. DNA polymerase I incorporation of fluorescently labeled nucleotides has been observed to occur on surface-mounted DNA molecules.\textsuperscript{(11)} The action of DNA polymerases is quite different from that of restriction endonucleases. Restriction endonucleases bind their target, often with little distortion to the DNA helix.\textsuperscript{(88)} In contrast, DNA polymerase I has a more complicated action. The enzyme binds to a nick site and then essentially wraps around the helix, using 5'-3' exonuclease activity to remove bases, and 5'-3' template addition to add new nucleotides.\textsuperscript{(89,90)} Surface mounted molecules are therefore biochemically active. Severe adsorption of the DNA helix to the surface would preclude any meaningful degree of template addition or exonuclease activity.

Since optical mapping of genomic DNA has been used to analyze entire microbial genomes, similar approaches are being used to make a restriction map of the entire human genome. A pilot project to map the entire human genome using megabase-sized DNA molecules was recently completed. Molecules, directly extracted from peripheral blood, were mapped with PacI. 0.6 human genome equivalents were mapped at 40-kb resolution, using genomic fragments of depth of 2.1 Mb. Analysis of the contigs formed showed good correspondence with suitably modified Lander–Waterman\textsuperscript{(19)} physical mapping criteria in terms of the number and depth of overlapped genomic fragments. Goals are simultaneously to complete the human reference map to include 10–15 x coverage and to link with other physical maps by the alignment of restriction mapped BAC contigs. The utility of this map will be to facilitate assembly of sequence from the Human Genome Initiative. Optical mapping systems could potentially be used for large scale genomic analysis and as a means to perform population-based genomic studies such as analysis of human disease genes or characterization of breakpoints in tumors.

44. J. Jing, (manuscript in preparation).

In recent years, there has been considerable interest in developing gene-targeting drugs. Synthetic molecules that bind effectively with high sequence specificity to a desired target in a particular “destined” gene sequence are of major interest in medicine and molecular biotechnological research. They show hope for the development of gene therapeutic agents, high-precision diagnostic devices for genetic analysis and convenient tools for nucleic acid manipulations. Peptide nucleic acid (PNA) is a nucleic acid analog in which generally a 2-aminoethylglycine linkage replaces the normal phosphodiester backbone. A methyl carbonyl linker connects standard (in some case unusual) nucleotide bases to this backbone at the amino nitrogens. The nonprototype, yet interesting, chemistry of this synthetic molecule has three important consequences: peptide nucleic acids are neutral molecules, they are achiral and they are not susceptible to any hydrolytic (enzymatic cleavage). Despite these great differences from DNA, PNA is capable of sequence-specific recognition of DNA and RNA obeying the Watson–Crick hydrogen bonding rules and the hybrid complexes thus formed exhibit extraordinary thermal stability and unique ionic strength properties. Regarding applications of PNA, one obvious question is what the advantage is cell extracts or inside a living cell. It is capable of sequence-specific recognition of DNA and RNA obeying a Watson–Crick hydrogen bonding scheme and the hybrid complexes exhibit extraordinary thermal stability and unique ionic strength effects. It also recognizes duplex homopurine sequences of DNA to which it binds by strand invasion, forming a stable PNA–DNA–PNA triplex with a looped-out DNA strand. This potential synthetic mimic of DNA, since its discovery in 1991, has attracted great attention within medicinal chemistry and molecular biology and also various other fields such as organic and physical chemistry because of its interesting chemical and physical properties. It has been regarded to have great potential for both diagnostic and pharmaceutical applications. In vitro studies have shown successful attempts to use PNA as an inhibitor for both transcription and translation of specific genes. This holds promise for using PNA for antigen and antisense therapy. However, the most exciting use of PNA, as an antisense or antigen drug, requires an efficient and safe method to deliver PNA into living cells, a problem that still remains to be solved.

1 INTRODUCTION

Historically, PNA originates from attempts during the 1980s in the Danish organic chemist Ole Buchardt’s laboratory to develop new DNA sequence-specific reagents. Based on the observation with flow linear dichroism (LD) that α-helical poly-γ-benzylglutamate (PBG) forms stacking complexes with aromatic chromophores, it was suggested that PBG with alternating nucleobases and acridine moieties instead of phenyls might bind sequence selectively to duplex DNA by combined Hoogsteen base-pair (bp) formation and intercalation with the helix backbone in the major groove. The suggested compound was tentatively named peptide nucleic acid, PNA.

Today’s PNAs (Figure 1a and b) are DNA analogs in which generally a 2-aminoethylglycine linkage replaces the normal phosphodiester backbone. A methyl carbonyl linker connects standard (in some case unusual) nucleotide bases to this backbone at the amino nitrogens. The nonprototype, yet interesting, chemistry of this synthetic molecule has three important consequences: peptide nucleic acids are neutral molecules, they are achiral and they are not susceptible to any hydrolytic (enzymatic cleavage). Despite these great differences from DNA, PNA is capable of sequence-specific recognition of DNA and RNA obeying the Watson–Crick hydrogen bonding rules and the hybrid complexes thus formed exhibit extraordinary thermal stability and unique ionic strength properties. Regarding applications of PNA, one obvious question is what the advantage is...
of using PNA over DNA. Scientists have been working towards the development of a wide range of applications for PNAs since 1991. These can be generalized in four categories: first, its use as a tool for molecular biology and biotechnology; second, towards the development of a gene-targeted drug using antigen or antisense strategy; third, the use of PNA for diagnostics purpose and towards the development of biosensors; and fourth, the study of basic chemistry to address the problems related to improvement of PNA. As we review PNA applications, we shall focus on various analytical techniques necessary for the synthesis and characterization of novel PNA constructs, their development and application as gene therapeutic agents and detection systems for genetic analysis, and finally on understanding the physicochemical aspects of PNA and PNA–nucleic acid complexes.

2 CHEMICAL METHODS – CHEMISTRY AND SYNTHESIS

2.1 Synthesis

The backbone of PNA carries 2- aminoethylglycine linkages to replace the normal phosphodiester backbone of DNA. The nucleotide bases are connected to this backbone at the amino nitrogens through a methylene carbonyl linker (Figure 1a and b). Since PNAs are achiral molecules, there is no need to develop a stereoselective pathway for their synthesis. PNA oligomers are prepared following the well-established solid-phase peptide synthesis protocols. The protecting scheme for the amino groups of PNA monomers is based on either Boc or Fmoc chemistry. In principle, PNA oligomers are synthesized using standard solid-phase peptide synthesis procedures with a (methylbenzhydryl)amine polystyrene resin as the solid support. Several modifications of PNA, related to various functional requirements, have been reported. It is possible to modify PNA oligomers either by coupling amino acids during solid-phase synthesis or by attaching compounds that contain a carboxylic acid group to the exposed N-terminal amine group. The postsynthetic modification process employs coupling to an introduced lysine or cysteine residue in the PNA. A bis-PNA is prepared in a continuous synthesis process by connecting two PNA segments via a flexible linker composed of multiple units of either 6-aminohexanoic acid or 8-amino-3,6-dioxoactanoic acid. It has been reported that changing cytosine to pseudoisocytosine in the Hoogsteen strand abolishes the pH dependence of a DNA-PNA–DNA triplex without affecting the stability of the triplex.

2.2 Purification

Post-synthesis procedures involve cleaving PNA oligomers from the solid support by treatment with either anhydrous hydrogen fluoride or trifluoromethanesulfonic acid, as done in traditional peptide chemistry, followed by high-performance liquid chromatography (HPLC) purification. In some cases, crude PNA products are cleaved from the solid matrix by treatment with trifluoroacetic acid–m-cresol (4:1) and precipitated in ice-cold diethyl ether and thereafter dissolved in 0.1% trifluoroacetic acid solution. PNA molecules are further purified and characterized by reversed-phase HPLC followed by matrix-assisted laser desorption ionization/time-of-flight mass spectrometry (MALDI/TOFMS). We shall discuss this later.

3 ELECTROPHORETIC AND HYBRIDIZATION TECHNIQUES

PNAs can hybridize to complementary DNA and RNA sequences in a sequence-dependent manner obeying the Watson–Crick hydrogen bonding scheme. A unique multiple-stranded triplex structure containing both Watson–Crick and Hoogsteen base pairing is also possible from a 2:1 PNA–DNA complex. The mechanistic pathway for the formation of the triplex is known as “strand-invasion”. PNA–DNA hybridization is more affected by base mismatches than corresponding DNA–DNA hybridization. Surprisingly, PNA can maintain sequence discrimination up to the level of a single mismatch. High-affinity binding, a high level of mismatch discrimination and the novel strand-invasion property have allowed researchers to develop several PNA-based applications, employing the basic principles of electrophoresis and hybridization, in conjunction with molecular biology/biotechnology, medicine (as gene-targeted drug) and diagnostics.

3.1 PNA as a Tool for Molecular Biology/Biotechnology Research

The following applications evidence the potential of PNAs as a tool for molecular biology and biotechnology...
and justify the development of new methodologies related to that.

3.1.1 PNA Hybridization as an Alternative to Southern Hybridization Technique

Southern hybridization is perhaps one of the most widely used techniques in molecular biology. It is used to analyze genetic loci, employing fragments of defined length obtained from either polymerase chain reaction (PCR) or restriction digestion. The great utility of this core molecular biological technique is derived from its ability to predict both size and sequence information and information regarding the genetic context. However, the disadvantages of this process include laborious multistep washing steps and poor sequence discrimination between closely related species.

PNA pregel hybridization simplifies the process of Southern hybridization and eliminates the cumbersome postseparation, probing and washing steps. It is possible to use labeled (fluoresceinated) PNA oligomers as probes and hybridize them to a denatured DNA sample at low ionic strength, and the mixture is thereafter directly subjected to electrophoresis for size separation. Single-stranded DNA fragments are separated on the basis of their length. The charge-neutral backbone of peptide nucleic acid allows for hybridization at low ionic strength and renders a much higher mobility to the complex compared with the excess unbound PNA. The hybrids are blotted (transferred) on to a nylon membrane, dried, ultraviolet (UV) cross-linked and detected using standard chemiluminescent techniques. It is also possible to detect the bound PNA by direct fluorescence detection using capillary electrophoresis (CE) (to be discussed later). The strong binding of PNA to DNA allows the PNA–DNA duplex to remain intact under conditions where the normal DNA–DNA duplex tends to disrupt. This allows sequence-specific detection with simultaneous size separation of the target DNA following a simple and straightforward protocol. Consequently, the analysis is much faster than conventional Southern hybridization technique.

3.1.2 Nucleic Acid Purification

PNAs have also been used to purify target nucleic acids. The purification process is based on its unique hybridization property. PNAs carrying six histidine residues can be used to purify target nucleic acids by nickel affinity chromatography. Biotinylated PNAs in combination with streptavidin-coated magnetic beads may be used to purify *Chlamydia trachomatis* genomic DNA directly from urine samples. Inspite of being simple, fast and straightforward, this “purification by hybridization” approach has a number of drawbacks. First, it requires knowledge of a target sequence and depending upon that a capture oligomer has to be synthesized for each different target nucleic acid. Since the target sequences for the short pyrimidine PNA, the most efficient probe for strand invasion, are prevalent in large nucleic acids, such short PNAs can be used as generic capture probes for purification of large nucleic acids. It has been shown that a biotin-tagged PNA–thymine heptamer could be used to purify efficiently human genomic DNA from whole blood by a simple and rapid procedure.

3.1.3 Enhanced Polymerase Chain Reaction Amplification

PCR is used to amplify unique regions of DNA so that they can be detected in large genomes. PCR, now widely used in research laboratories and hospitals, relies on the ability of DNA-copying enzymes to remain stable at high temperatures. The three steps in the PCR (carried out in the same vial), viz. the separation of the strands, annealing the primer to the template and the synthesis of new strands, take less than 2 min. At the end of a cycle, each piece of DNA in the vial has been duplicated. Each newly synthesized DNA piece can act as a new template, so after 30 cycles, 1 million copies of a single piece of DNA can be produced. Taking into account the time it takes to change the temperature of the reaction vial, 1 million copies can be ready in about 3 h.

PCR has been widely used for various applications including the amplification of variable number of tandem repeat (VNTR) locus for the purpose of genetic typing. However, in some cases there are preferential amplifications of small allelic products relative to large allelic products. This results in an incorrect typing in a heterozygous sample. PNA has been used to achieve an enhanced amplification of VNTR locus D1S80. This renders a genetic pattern which is fairly easy to decipher. Small PNA oligomers are used to block the template. This makes the latter unavailable for interstrand and intrastrand interaction during reassociation. However, the primer extension is not hindered. During primer extension, polymerase displaces the PNA molecules from the template and extends the primer to completion. This application demonstrates the potential of PNA for PCR amplification where fragments of different sizes are more accurately and even amplified. As the probability of differential amplification is less, the risk of misclassification is greatly reduced.

A recent report by Misra et al. has demonstrated that PNA–DNA chimera lacking the true phosphate backbone can actually act as a primer for the polymerase reaction catalyzed by DNA polymerases. The analog, (PNA)_{19}-T_{7}G-OH, consists of 19 bases in the PNA part followed by a dinucleotide (T_{7}G-OH) with a single...
phosphate and a free 3’-OH terminus. This chimera, when annealed with a complementary RNA or DNA template strand, can be used as an efficient primer to catalyze the addition of nucleotide by polymerase enzymes. The primer is recognized by two reverse transcriptases and also by the Klenow fragment of *Escherichia coli* DNA polymerase I. From the results it has been proposed that the phosphate backbone of the template primer may not be essential, at least not in this case, for recognition and binding by the polymerases. The results also suggested that the diameter of the duplex region is a more critical factor than the phosphate backbone regarding the template-primer reaction and accommodating the same within the binding domain of the enzyme.

### 3.1.4 PNA and S1 Nuclease as Artificial Restriction Enzymes

S1 nuclease degrades single-stranded nucleic acids releasing 5’-phosphoryl mono- or oligonucleotides. The enzyme is basically a glycoprotein with a carbohydrate content of 18%. It is extensively used to remove the single-stranded overhangs of DNA fragments, RNA transcript mapping and construction of unidirectional deletions. PNA in combination with S1 nuclease can act as an “artificial restriction enzyme” system. Homopyrimidine PNA oligomers can hybridize with the complementary targets on dsDNA via a strand invasion mechanism, leading to the formation of looped-out noncomplementary DNA strands. Upon treatment by nuclease S1, the single-stranded DNA part is cut into well-defined fragments. The binding of two PNAs to two adjacent targets, on either the same or opposite DNA strands, essentially opens up the entire region making the substrate more accessible for the nuclease digestion and thereby increasing the cleavage efficiency.\(^5\)

### 3.1.5 PNA-assisted Rare Cleavage

Peptide nucleic acids, in combination with methylases and other restriction endonucleases, can act as rare genome cutters.\(^9\) The technique, called the PNA-assisted rare cleavage (PARC) technique (Figure 2), employs the strong and sequence-specific binding of PNAs, preferably bis-PNAs, to short homopyrimidine sites on large DNA molecules, e.g. yeast or \(\lambda\) DNA. The PNA binding site is selected in such a fashion that it overlaps with the methylation/restriction enzyme site on the DNA. When bound to DNA, this PNA molecule will efficiently shield the site from enzymatic methylation whereas the other so-called naked or unprotected methylation/restriction sites will be methylated. After the removal of bis-PNA, it is possible to cleave the whole DNA by restriction enzymes into a limited number of pieces. DNA is efficiently protected from enzymatic digestion due to methylation in most of the sites and is only cleaved through those sites which were previously bound to PNA. Thus, short PNA sequences, particularly positively charged bis-PNAs, combined with various methylation/restriction enzyme pairs, are capable of providing a new class of genome rare cutters.

### 3.1.6 Determination of Telomere Size

The standard procedure for the determination of telomere length involves Southern blot analysis of genomic DNA and provides a range for the telomere length of all chromosomes present. Another approach includes the use of fluorescein-labeled oligonucleotides and monitor the in situ hybridization of them to telomeric repeats. Much better and more quantitative results are obtained when DNA oligonucleotides are replaced by fluorescein-labeled PNAs, as shown by Lansdorp et al.\(^40\) This PNA-mediated approach allows accurate estimates of the telomeric length to be made. In situ hybridization of fluorescein-labeled PNAs to telomeres is faster than DNA hybridization and requires a lower concentration of the probe. Low photobleaching and an excellent signal-to-noise ratio make it possible to quantitate telomeric repeats on individual chromosomes in this way. It is likely that variations of this approach can be applied to other repetitive sequences to achieve similar results.

### 3.2 Possible Applications of PNA in Medicine

The potential of PNA to act as a genetic drug has been well appreciated. It is clearly a substantial lead in gene therapeutic drug design provided that we have well-identified targets for it. Two general strategies

---

3.2 Possible Applications of PNA in Medicine

The potential of PNA to act as a genetic drug has been well appreciated. It is clearly a substantial lead in gene therapeutic drug design provided that we have well-identified targets for it. Two general strategies
are applicable towards gene therapeutic drug design (Figure 3). Oligonucleotides or their potential analogs can be designed to recognize and hybridize to complementary sequences in a particular gene and thereby inhibit its transcription (the antisense strategy). Peptide nucleic acids are biologically and chemically stable and have significant effects on replication, transcription and translation, as revealed from in vitro measurements. Moreover, so far no signs of general toxicity of PNA have been observed. PNA binding to mRNA interferes with translation, PNA–dsDNA strand displacement complexes inhibit protein binding and block RNA polymerase elongation.

3.2.1 Transcription Arrest by PNA: the Antigene Effect

Homopyrimidine PNA standard displacement complexes form extremely stable strand-displacement complexes upon binding to dsDNA. In principle, they should be capable of working as antigene agents. In reality, such complexes are indeed capable of affecting the process of transcription involving both prokaryotic and eucaryotic RNA polymerases in vitro. PNA bound to a promoter region is capable of blocking the DNA access of the corresponding polymerase protein. PNA strand-displacement complexes, located far downstream from the promoter, can also efficiently block polymerase progression and transcription elongation and thereby produce truncated RNA transcripts. This requires that the PNA target, i.e. the DNA poly-purine target, must be present in the gene of interest. It has been found that even an 8-mer PNA (T8) is able to block phage T3 polymerase in action. The effect of having a PNA target within a promoter region on gene expression has been demonstrated for IL-2R α gene. The PNA-DNA triplex thus can arrest transcription in vitro and can act as an antigene agent. However, one of the major obstacles to applying PNA as an antigene agent is that the strand invasion or the formation of strand displacement complex occurs very slowly at physiological salt concentration. Several modifications of PNA have shown improvement in terms of binding. Modifications of PNA by the incorporation of intercalators, positively charged lysine residues, chemically linking the ends of the Watson–Crick and Hoogsteen PNA strands to each other or pH-independent psuedoiso-cytosines into the Hoogsteen strand can drastically increase the association rates with dsDNA. A recent report by Lee et al. has demonstrated that PNA as well as the PNA–DNA chimera complementary to the primary site of the HIV-1 genome can completely block priming by tRNAlys and consequently the in vitro initiation of the reverse transcription by HIV-1 RT. Their observations suggest that oligomeric PNA target critical regions of the viral genome are likely to have a strong therapeutic potential for interrupting multiple steps involved in the replication of HIV-1.

Figure 3 Antigene and antisense strategy: cells can be treated with an antigene oligonucleotide (such as PNA), which can bind to a (specific) complementary sequence in the DNA and inhibits transcription of the gene. On the other hand, an antisense oligomer can hybridize to a specific mRNA sequence to inhibit the expression of a protein at the level of translation.
It has been found that under physiological salt conditions, binding of PNA to supercoiled plasmid DNA is faster than linear DNA.\(^{(44,46)}\) This indicates that the topology of DNA is an important factor or criterion for determining the binding rate. Since transcriptionally active chromosomal DNA is usually negatively supercoiled, this could be of relevance for PNA binding in vivo. It has also been shown that binding of PNA to dsDNA is enhanced when the DNA is being transcribed. Such transcription-mediated PNA binding occurs three times as efficiently when the PNA target is situated on the non-template strand than on the template strand. As transcription mediates template strand-associated complexes which arrest further elongation, the action of RNA polymerase results in repression of its own activity, i.e., suicide transcription.\(^{(48)}\) These findings are highly relevant for the possible future use of PNA as an antigene agent.

It is important to mention that there are also reports regarding the ability of PNA to activate transcription which, however, is not related to its antigene effect. It has been demonstrated that the looped-out single-stranded structure formed as a result of strand invasion can also act as efficient initiation sites for E. coli and mammalian RNA polymerases in which the polymerase might start transcription using the single-stranded loop as a template.\(^{(49)}\) This is consistent with the affinity of RNA polymerase for single-stranded DNA and its ability to transcribe single-stranded DNA.

### 3.2.2 Translation Arrest by PNA: the Antisense Effect

The principal mechanism of antisense effects by oligodeoxynucleotides is believed to be either a ribonuclease H (RNase H)-mediated cleavage of the RNA strand in oligonucleotide–RNA heteroduplex or a steric blocking of the translation machinery at the oligonucleotide–RNA complex.\(^{(50)}\) Oligodeoxynucleotide analogs, such as phosphorothioates, activate RNase H and thus hold the promise of working as efficient antisense agents. However, they have also been shown to exhibit nonspecific effects. PNA–RNA duplexes, on the other hand, cannot act as substrates for RNase H. Therefore, the antisense activity of PNA has to be dependent on other mechanisms. In fact, the antisense property of PNA is based on the steric blocking of either RNA processing, transport into cytoplasm or translation. In vitro translation experiments involving rabbit reticulocyte lysates have shown that both duplex- (mixed sequence) and triplex-forming (pyrimidine-rich) PNAs are capable of inhibiting translation at targets overlapping the AUG start codon.\(^{(50)}\) Triplex-forming PNAs are able to hinder the translation machinery at targets in the coding region of mRNA. However, translation elongation arrest requires a \((\text{PNA})_2\)–RNA triplex and thus needs a homopurine target of 10–15 bases. However, duplex-forming PNAs are not capable of this. Triplex-forming PNAs can inhibit translation at initiation codon targets and ribosome elongation at codon region targets.

A recent report by Mologni et al.\(^{(51)}\) has demonstrated the effects of three different types of antisense on the in vitro expression of PML/RAR\(_\alpha\) gene. The first one was complementary to the first AUG (initiation) site. The second one was capable of binding to a sequence in the coding region that includes the second AUG, the starting site for the synthesis of an active protein. The third PNA was capable of binding to the 5′-untranslated region (5′-UTR) of the mRNA, the point of assembly of the translation machinery. These three PNAs provided an efficient inhibition when used together even at concentration much below the critical concentration used for each individual. This indicates that the PNA targeting of RNA molecules such as PML/RAR\(_\alpha\) require effective blocking of different sequences on the 5′ part of the messenger. A 5′-UTR PNA target can be used as efficiently as an AUG target to achieve an antisense activity of PNA and a more effective translation inhibition can be achieved by combining PNA directed towards 5′-UTR and AUG regions.

#### 3.2.3 Cellular Effects and Delivery of PNA

It is important to add here a few lines regarding the effect of PNA on intact cells and problems related to its delivery. Effects of PNAs on intact cells have only been demonstrated upon cellular microinjection and an antisense activity against a transfected gene has been established in this way.\(^{(10,18)}\) However, the cellular uptake of PNA is very poor, which is still considered the major obstacle against the prospective use of PNA as a gene therapeutic drug. Efforts are being made to increase the cellular uptake of PNA, especially by modifying the molecule itself or by conjugating suitable ligands, which will result in an enhanced physical or receptor-mediated cellular uptake. Incorporation of “guide” sequence or some “vector” peptides might make it more attracted to the cell membrane and will eventually help in docking the desired PNA at the cell surface. A recent report by Aldrian-Herrada et al.\(^{(52)}\) showed that a peptide nucleic acid is more rapidly internalized in culture neurons when coupled to a delivery peptide (retro-inverso peptide). A PNA antisense for the AUG translation initiation region of prepro-oxytocin mRNA was coupled to the vector retro-inverso peptide. The conjugated construct was internalized by cultured cerebral cortex neurons within minutes. Penetration of single PNA molecules was rather slow. It has been found that both PNA and the peptide–PNA construct lowered
the amounts of mRNA coding for prepro-oxytocin in these neurons. This shows that PNAs guided by suitable vector peptides can act as powerful antisense agents.

Another strategy which has been adapted to improvise the delivery of PNA is to incorporate it into some kind of delivery vehicles (vesicles), e.g. liposomes. However, the assessment of the latter method has to await tests in a real in vivo system involving animal models.

3.3 PNA as a Diagnostic Tool

Nucleic acid hybridization forms the basis for the diagnosis of inherited or infectious diseases. High-affinity binding of PNA oligomers to its complementary sequences provides a clear advantage for molecular recognition and leads to the development of new applications of PNA, especially as a diagnostic probe for detecting genetic mutations. Based on its unique hybridization property, a number of applications have been described utilizing PNA as a probe for the detection of genetic mutation and mismatch analysis.

In this section, we describe some of the developments related to the use of PNA as a probe to detect genetic mutation and corresponding mismatch analysis, confirming its potential as a diagnostic tool for different clinical applications. Fundamental principles related to each of these applications will also be discussed.

3.3.1 Single Base-pair Mutation Analysis Using PNA-directed Polymerase Chain Reaction Clamping

Amplification of the target nucleic acid to detectable quantities by the PCR technique is an important step regarding the detection of genetic diseases, especially those related to the single base pair mutations. The higher specificity of PNA binding to its complementary nucleic acid, higher thermal stability of a PNA–DNA duplex compared with the corresponding DNA–DNA duplex and its inefficiency to act as a primer for DNA polymerases are the basis for novel methodology. Figure 4 depicts the schematic representation of the PCR cycle and the strategy employed for this PNA-directed PCR clamping. This procedure includes a distinct annealing step involving the PNA targeted against one of the PCR primer sites. This takes place at a temperature higher than that for PCR primer annealing and thus PNA is selectively bound to the DNA molecule. The PNA–DNA complex formed at one of the primer sites can effectively block the formation of a PCR product. It was also found that PNA is able to discriminate between fully complementary and single mismatch targets in a mixed target PCR. Sequence-selective blockage by PNA allows suppression of target sequences that differ by only one base pair. Also, this PNA clamping was able to discriminate three different point mutations at a single position, as demonstrated in a model system by Örum et al.(13)

Based on the principle of PNA-mediated PCR clamping,(13) a study by Thiede et al.(15) has demonstrated a novel approach for simple and sensitive detection of mutations in the ras proto-oncogenes. The strategy behind this is schematically represented in Figure 4. Chromosomal DNA is hybridized to a 15-mer PNA complementary to a normal wild-type sequence surrounding codons 12 and 13. In the case of the normal Ki-ras, formation of a PNA–DNA duplex will be favored owing to its high melting temperature and thus it would sterically hinder the annealing of overlapping primer sequence, thus preventing the normal sequence from appropriate PCR amplification. In the case of mutant alleles, the melting temperature of the PNA/DNA is reduced and the primer can outcompete PNA annealing to carry on preferential amplification of mutant sequences.

Figure 4 Mutation analysis using PNA-directed PCR clamping: schematic representation of the strategy for the PCR cycle involving PNA-directed clamping. In case of the normal (wild type) DNA, the bound PNA will sterically hinder annealing of a partially overlapping primer sequence, thus preventing the normal sequence from appropriate PCR amplification. In the case of mutant alleles, the melting temperature of the PNA/DNA is reduced and the primer can outcompete PNA annealing to carry on preferential amplification of mutant sequences.
3.3.2 Screening for Genetic Mutations by Capillary Electrophoresis

Most of the powerful separation techniques for biomolecules are based on electrophoresis, i.e. the migration of electrically charged species in solutions under the influence of an electric field. In principle, to achieve the separation of two species, their electrophoretic mobilities, $\mu$, must be different. The mobility, $\mu$, is given by Equation (1):

$$
\mu = \frac{v}{E} = \frac{Q}{f}
$$

where $v$ and $Q$ are the electrophoretic velocity and the electrophoretic charge of the analyte, respectively, $E$ is the electric field strength and $f$ is the friction coefficient. For DNA in free solution, both $Q$ and $f$ are proportional to the contour length of the DNA, say $L_C$. In fact, it has been experimentally verified that in free solution the mobility is independent of the DNA size. A size-dependent mobility is generally obtained by using a separation medium such as a gel or a polymer solution. Instead of using a separation medium, a size-dependent mobility of DNA can also be obtained by breaking the scaling symmetry between the electrical and frictional forces either by changing the charge or the mass distribution. The electrophoresis in slabs of polyacrylamide or agarose gels has been the preferred method for separation of DNA for a long time. In recent years, especially owing to technological advances, there has been considerable interest in CE of DNA.

In CE, separation takes place in a long, thin capillary (typically 50–80 cm long, inner diameter ∼10–300 µm), generally made of fused silica. A portion of the coating is removed at the end of the capillary to detect the analyte. As the analyte passes the detection window it can be visualized by UV or laser-induced fluorescence (LIF) detection which is accomplished on-line and can be automated. CE is capable of analyzing minute amounts of sample (typically of the order of picograms to femtograms). However, the major disadvantage compared with slab-gel electrophoresis is that generally it is not possible to analyze more than one sample at a time.

The most important phenomenon described in CE is known as electroosmosis, an electrokinetic effect described as the motion of a liquid relative to a fixed charged surface caused by an electric field. Under the influence of an aqueous solution, the silica surface of the fused-silica capillaries forms silanol groups (SiOH$_2^+$, SiOH or SiO$^-$). This depends upon the pH values and for a pH value above 3–4, the silica surface will be negatively charged. These negative charges are counterbalanced by positive ions from the surrounding solution, forming an electrical double layer close to the surface (Figure 5).

Figure 5 Illustration of the Stern–Gouy–Chapman model of the electric double layer at the interface between the capillary wall and the electrolyte system. The arrows indicate the direction of electroosmotic flow through the capillary. Note: acidic silanol groups impart a negative charge on wall and counterions migrate towards cathode, dragging solvent along.

According to the model described by Stern, Gouy and Chapman, the electric double layer can be described as consisting of one inner, static layer of adsorbed counterions, known as the Stern layer, and an outer, mobile layer in which ions diffuse due to thermal motion, known as the Gouy–Chapman layer. When an electric field is applied over the capillary, the positive ions migrate towards the negative electrode, dragging the mobile liquid layer with them. Although the electric double layer is only about 100 Å thick, the electroosmotic flow is transmitted throughout the whole cross-section of the capillary. In electrically driven systems, the flow caused by electroosmosis shows a uniform velocity across the capillary diameter except in the double layer region close to the wall where the velocity approaches zero. This so-called plug-flow appears as a result of the uniform distribution of the driving force for electroosmosis along the entire length of the capillary. For a particular field strength, the magnitude and direction of the electroosmotic flow depend on the composition of the capillary surface and on the pH and ionic strength of the electrolyte solution. Owing to the strong electroosmotic flow towards the cathode, all species, irrespective of their charge, move towards the negative electrode. Thus positively and negatively charged species can be analyzed in the same run. As the electrophoretic mobility of a free polyelectrolyte (DNA) is independent of molecular weight because the electric driving force and the frictional force are both proportional to the length (Equation 1), it may appear that electrophoresis in free solution is not a convenient tool for DNA separation. However, if the scaling symmetry between electrical and frictional...
forces can be disrupted, by changing either the charge or mass distribution or the hydrodynamics, a size-dependent mobility can be achieved for DNA.

Carlsson et al.\textsuperscript{(14)} reported a novel, diagnostic method for the detection of genetic mutation using PNA as a probe for CE. The method is based on the unique hybridization of PNA and is sensitive enough to detect a single mismatch in the sample DNA. The model system consisted of four 50-mer single-stranded DNA fragments, one wild type and three mutant sequences (Table 1), representing a part of the cystic fibrosis transmembrane conductance regulator gene (CFTR). The probe was a 15-mer PNA oligomer with a sequence complementary to the wild-type sequence. The principle of the method is that PNA only binds to the DNA in the absence of any mutation in the particular region of the CFTR gene and it is possible to detect the presence of such a hybrid duplex using free solution CE. Separation of PNA–DNA duplexes was carried out at a high temperature (\(\sim 70^\circ\text{C}\)) (Figure 6a–c) and 50 mM ionic strength. At this temperature and ionic strength, only the hybrid duplex carrying the wild-type DNA sequences will be detected. The hybrid complex carrying single-mismatch DNA will be melted. Free PNA is not detected because it binds to the capillary wall. In another experiment, the PNA probe was added to a PCR preparation of the 142-mer wild-type CF fragments and the 139-mer three-base deletion fragments. When studied at 50°C, the PNA–DNA duplex was identified for the wild-type sequences but was not seen at all for the mutant.

In another study Nordén and co-workers. (unpublished observations) used free solution CE to detect point mutation in a 142-mer DNA fragment, which represents a vulnerable part of the p53 gene. The PNA probe used for this study was a 15-mer oligomer having sequence complementary to the wild-type p53 DNA (in this case the 15-mer DNA). The separation was carried out at a temperature below the thermal melting temperature, as determined from UV spectrophotometry, of the fully matched PNA–DNA hybrid, but above the thermal melting temperature of the PNA–DNA duplex carrying a single mismatch at the eighth position (corresponding to a mutation in the codon 175 of the p53 resulting in an altered P53 protein with an arginine replaced by a histidine). At this temperature, the fully matched duplex maintained its structural integrity and was detected by using UV or LIF.
Affinity electrophoresis, depending on the noncovalent gel-based technique, known as affinity electrophoresis.

bound species.

and permits the separation of the free oligomer from the chemistry of antisense oligonucleotides as the separation This method is also useful for studying the interaction to resolve free and bound PNA allows the measurement of elapsed time after mixing of oligonucleotide-to-PNA allows the measurement as a function of the separated components is measured as a function of time BIA measurement, it is possible to monitor the interacting component and the response is primarily independent of the nature of the molecules. In a real-time BIA measurement, it is possible to monitor the changes in the surface concentration on a timescale of the order of 0.1 s, which, in principle, is sufficient enough to determine typical biomolecular kinetic rate constants in the range $10^3 – 10^6 \text{ M}^{-1} \text{s}^{-1}$ (association) and $10^{-1} – 10^{-5} \text{s}^{-1}$ (dissociation).

Jensen et al., for the first time, reported an investigation of PNA–DNA/RNA hybridization using the BIAcore technique. The sensor chip used in this case was basically a thin gold surface covered with a layer of dextran that contained streptavidin chemically coupled to the dextran (Pharmacia sensor chip SA5). A biotinylated PNA [biotin-(eg1)₃-TGTACGTCACAACTA-NH₂; N- to C-terminal; note: PNA is generally written from N- to C-terminal] was used as a probe and it was immobilized to the streptavidin chip by employing the strong
coupling between biotin and streptavidin. By measuring the amount of bound substance (fully complementary and also various singly mismatched RNA and DNA oligonucleotides) as a function of time when a solution containing the complementary strands passes over the chip surface, the association kinetics were studied. The dissociation was correspondingly monitored by detecting the time dependence of the mass decrease as the surface was subsequently washed with buffer. It is also possible to regenerate the PNA surface by washing with HCl to remove the remaining hybridized products and perform consecutive studies with the same immobilized PNA. Assuming a two-state model, $A + B \rightleftharpoons AB$, the analysis of the hybridization kinetics was carried out. The dissociation kinetics, obtained from the dissociation part of the sensorgram (Figure 7), were analyzed using Equation (2):

$$[AB] = [AB]_0 e^{-k_d(t-t_0)}$$

where $[AB]_0$ represents the duplex concentration at time $t_0$ and $k_d$ is the dissociation rate constant. The association kinetics were analyzed with respect to the concentration dependence of the association rate by varying the concentration of the analyzed agent, $A$, in the mobile phase (Equation 3):

$$[AB] = \frac{k_d[A][B]_0}{k_d[A] + k_d} 1 - e^{-(k_s[A]+k_d)t}$$

Using $k_s[A] + k_d = k_s$ and measuring $k_s$ at different concentrations of $A$, the association rate constant can be obtained from the slope of the plot of $k_s$ versus $[A]$. The results indicated that the introduction of a single mismatch at the center of 15-mer PNA–DNA and PNA–RNA duplexes gives rise to marked changes in the kinetics of both hybridization and dissociation.\(^{66}\)

It is also possible to use a plain gold surface (e.g. BIAcore sensor chip J1) to immobilize PNA molecules carrying cysteine at the N-terminal side (Nordén and coworkers unpublished observations). The strong coupling between gold and sulfur was employed to immobilize the PNA molecule. This gives a better control over the surface coverage of the ligand and erroneous results due to nonspecific binding of ligands to the dextran layer can be eliminated. It is important to note that DNA has a very high affinity for gold and can be nonspecifically adsorbed on the surface without much effort. Direct addition of analyte DNA molecules to the sensor surface, to study its binding with PNA, might facilitate its adsorption to the gold surface. It is important to use short spacer molecules, e.g. mercaptohexanol, together with the ligand (probe) to form the PNA monolayer at the top of the sensor (gold) surface and prevent DNA molecules from being nonspecifically adsorbed to the surface.

### 3.3.3.2 Potentiometric Measurements Wang et al.\(^{16}\) have reported the use of PNA as a recognition probe for the electrochemical detection of the hybridization event employing chronopotentiometric measurements. The method consisted of four steps: probe (PNA) immobilization on to the transducer surface, hybridization, indicator binding and chronopotentiometric transduction. The carbon paste electrode used in this process contained the immobilized DNA or PNA probe. The hybridization experiment was carried out by immersing the electrode in the stirred buffer solution containing a desired target. The strong adsorptive accumulation of the PNA was exploited for preparing the PNA modified surfaces and this adsorptive immobilization of short PNA oligomers leads to very effective hybridization biosensors. The potentials were sampled at a particular frequency and the derivative signal was recorded against the potential. The sensor was challenged with various noncomplementary oligomers and chromosomal DNA, including a 15-mer oligonucleotide containing a single-base mismatch. However, their results suggest that, in mixtures with the complementary strand, the noncomplementary oligomers have a profound effect upon the target signal at the DNA biosensor and a negligible effect upon that observed at the PNA-coated electrode.

### 3.3.3.3 Single-base Mismatch Analysis Using Quartz Crystal Microbalance Traditionally, the quartz crystal microbalance (QCM) has been used to monitor mass or thickness of thin films deposited on surfaces and to study gas adsorption and deposition on surfaces in the monolayer and submonolayer regimes.\(^{66}\) The method has also been developed to use in liquid to apply it to the research areas related to electrochemistry or studying protein adsorption. The QCM is a very sensitive mass-measuring device. The resonant frequency of the crystal changes as a result of a minute weight increase on the surface. The
typical measurements include monitoring the shift in resonant frequency of the QCM due to mass changes. The technique also offers the possibility of obtaining additional information related to the dissipation factor, D, of the oscillator (the damping). Dissipation arises mainly owing to the internal friction and viscoelastic properties of the fluid. Recently, the method has developed further for use in liquids and simple techniques have been developed to measure dynamically changes in the dissipation of energy by the QCM operating in a liquid, e.g., due to adsorption on an electrode. Okahata et al.\(^6^2\) reported the quantitative detection of M13 viral DNA containing a 10-base insert by hybridization to a complementary, 5’-thiol-modified, 10-base DNA probe adsorbed on a QCM. There are reports concerning the use of QCM to study sequence-specific binding of GCN4-bZIP peptides to immobilized DNA strands\(^6^3\) and direct monitoring of DNA polymerase reactions on a QCM.\(^6^4\) It is obvious that in situ detection of a hybridization event is possible by using QCM transducers and the method of detection is not related to the need of using an optical or redox indicator. Since PNA hybridizes to complementary DNA strands with high affinity and sequence specificity, one might expect that immobilized PNA strands (or probes) would show an improved distinction between the closely related target sequences compared with an immobilized DNA probe. Wang et al.\(^6^5\) reported a QCM biosensor based on peptide nucleic acid probes. The PNA probes, which formed the monolayer on the gold QCM surface, contained a cysteine attached to the PNA core with the help of an ethylene glycol unit. Immobilized PNA, in such a system, is capable of differentiating between a fully complementary and single mismatch oligonucleotide and a rapid detection of mismatch sequences is possible by monitoring the frequency-time response of the PNA–QCM biosensor upon addition of fully complementary and mismatch sequences. The remarkable specificity of the immobilized probe provides rapid hybridization and allows the use of low ionic strength solutions of short probes. Such a mismatch sensitivity of PNA immobilized QCM biosensors could be of great importance for diagnostic applications, particularly for genetic screening, and therapy.

4 SPECTROSCOPIC AND CRYSTALLOGRAPHIC METHODS

In this section we discuss briefly the applications of various spectroscopic methods to characterize the properties of PNA and the PNA–DNA complexes. We also discuss crystallography and its application to determining the structure of PNA and, finally, different computational techniques in connection with PNA applications.

4.1 Electronic Spectroscopy

In this section we consider different aspects of PNA applications related to ultraviolet/visible (UV/VIS) absorption spectroscopy and dichroic measurements.

4.1.1 Ultraviolet and Visible Absorption Spectroscopy

The UV absorption spectra of aqueous solutions of nucleic acids have been known since 1960. The absorption spectrum for polymeric nucleic acid(s) has been well characterized and is known to exhibit a characteristic maximum at 260 nm, a minimum around 230 nm and a second maximum below 200 nm.\(^6^6\)-\(^6^7\) Perhaps the simplest application of absorption spectroscopy to PNA is related to its concentration determination. In general, the relative mean molecular mass of a nucleotide is taken as 330 and the molar absorptivity of natural native double stranded DNA is considered as \(\varepsilon_{260} = 6600\ M^{-1}\ cm^{-1}\). In general, an absorbance at 260 nm \((A_{260})\) of 1.0 in a 1-cm cell corresponds to a DNA concentration of 50 \(\mu\)g mL\(^{-1}\). Molar absorptivities of single-strand DNA oligomers have been calculated from the base composition as a sum of the absorptivities of DNA monomers (mononucleotides) using Equation (4):

\[
\varepsilon_{260} = 15.3n_A + 7.4n_C + 11.7n_G + 9.3n_T(\times10^3\ M^{-1}\ cm^{-1})
\]

(4)

where \(n_i\) denotes the number of bases of type \(I\).\(^6^8\)-\(^7^0\) This equation has also been refined for a nearest neighbor model and the sequence dependence of the absorptivity of a ssDNA can be calculated using Equation (5):

\[
\varepsilon_{260} = \sum_{i=1}^{N-1} \varepsilon(B_i, p_{i+1}) - \sum_{i=2}^{N-1} \varepsilon(B_i, p)
\]

(5)

where \(N\) is the total number of bases and \(\varepsilon(B_i, p_{i+1})\) and \(\varepsilon(B_i, p)\) are the molar absorptivities \((M^{-1}\ cm^{-1})\) of the dinucleoside phosphates and mononucleotides, respectively, counted from the 5’-end.\(^7^1\) The end nucleotides are not included in the second summation. However, the molar absorptivities for PNA monomers are not as well established as they are for DNA or RNA monomers. It is too much of a simplification to assume that a PNA oligomer should have the same molar absorptivity as its DNA or RNA counterpart. Since the backbone is different for this synthetic mimic, it is obvious that it could make a different kind of perturbation of the \(\pi\)-system of the nucleobases. Also, different stacking of the bases could give rise to a different extent of hypochromicity. The latter can be minimized if the absorption measurement is carried out at a high temperature (\(>75\)–80°C). Once the molar absorptivity of a PNA sequence has been calculated, the concentration of the stock solution can be
The concentration of a PNA oligomer is determined in the following way. Concentration determination is based on the absorptivities of DNA monomers and effective \( \varepsilon_{260} \) per single strand is calculated by using Equation (4). A value of 3000 M\(^{-1}\) cm\(^{-1}\) can also be used\(^{(46)}\) for the PNA oligomers containing pseudoscytoses (J bases).

Absorption spectroscopy is also important in PNA applications to monitor the hybridization of appropriate single strands to form the corresponding duplex, both pure and hybrid, structures. In general, solutions of single strands are heated to 80°C followed by adjustment of concentration (~2–3 mM per strand) from absorption measurements and the respective single-strand solutions are allowed to mix at that temperature. This is followed by a slow cooling step to ensure proper annealing of the strands.

The thermal melting temperature, \( T_m \), defined as the temperature at which 50% of the complexes have been dissociated, gives an idea of the stability of the PNA–PNA or PNA–DNA duplex. In principle, the thermal melting temperature (and also entropy and enthalpy) of a PNA duplex, pure and hybrid, is estimated by monitoring the change in absorption at 260 nm at different temperatures and the corresponding plot of absorbance versus temperature gives the thermal melting profile of a PNA duplex. Absorption melting provides information about different structural transitions. However, sometimes some information related to structural transitions is invisible in absorption melting owing to some associated factors, e.g. self-stacking and self-melting. It is often possible to overcome this problem by studying the circular dichroism (CD) melting, which can also provide supplementary information to complement the absorption melting study. The properties of PNA–PNA and PNA–DNA duplexes have been extensively investigated by employing absorption spectroscopy. The PNA oligomer H-TGTACGTCAACTA-NH\(_2\) forms an antiparallel duplex with complementary DNA with a \( T_m \) value of 70°C. The corresponding DNA–DNA complex has a \( T_m \) of only 53°C. However, the corresponding parallel duplex shows a transition temperature of 56°C.\(^{(4)}\) The thermal stability of PNA–RNA duplexes is higher than that for PNA–DNA duplexes.\(^{(46)}\) The increased thermal stability of PNA–PNA duplexes relative to the corresponding DNA–DNA duplexes is fundamentally due to the absence of any significant electrostatic repulsion between the two strands in the former.

The stability of PNA–DNA hybrids is not very much affected by changes in ionic strength, except in the limit of low ionic strength where the stability increases. Owing to the higher sequence specificity of PNA upon binding to nucleic acids, incorporation of any mismatch in the duplex considerably affects the thermal melting temperature of the heteroduplex. For the heteroduplex corresponding to the PNA sequence H-egl-GGCAGTGCCTCACAA-NH\(_2\) (C-terminal), and its full complementary DNA 5'-TTGTGAGGCGACTGCC-3', a mismatched incorporation of A in the eighth position of the DNA sequence, in place of G, reduces the \( T_m \) from 72.3 to 58.1°C (Table 2) (Nordén and co-workers unpublished observations).

Homopyrimidine PNA s binds complementary DNA sequences to form (PNA)\(_2\)–DNA triplex, and well-defined melting curves are obtained for these structures. The stability of the complexes depends on the length of

the oligomers in a regular manner with an increase in $T_m$ of approximately 10°C per base pair. For identical decamer sequences (antiparallel duplex), the $T_m$ corresponding to PNA–PNA, PNA–DNA and DNA–DNA sequences are 67, 51 and 33.5°C, respectively. However, the parallel PNA–PNA complex ($T_m = 47°C$) is still considerably more stable than the corresponding parallel DNA–DNA duplex.

4.1.2 Circular Dichroism and Linear Dichroism

CD and LD spectroscopic techniques early unveiled important structural aspects of PNA and PNA–nucleic acid hybrids.

4.1.2.1 Circular Dichroism

CD is the differential absorption of left and right circularly polarized light ($CD = A_l - A_r$). Chiral molecules, i.e. molecules having nonsuperimposable mirror images, exhibit characteristic optical activity, i.e. they induce a rotation of the plane polarized light, and show an intrinsic CD. An achiral molecule has an identical mirror image and it does not show any CD. However, if an achiral molecule interacts with a chiral environment, the former may gain some optical activity through coupling of the two systems and may, in turn, show an induced CD. When a supermolecular structure includes a set of chromophores, assembled into a helical structure, the coupling between transitions may also generate a considerable amount of CD signal. The CD spectrum of a particular molecule is very sensitive to changes in the secondary structure and is useful for the detection of conformational changes of the molecule, e.g. the secondary structure of DNA and protein.

Since PNA contains an achiral backbone, it does not show any CD spectrum. However, certain modifications on the backbone structure and its conjugation with complementary DNA and RNA sequences to form hybrids render the potential for using it as a probe in CD studies (Figure 8a–c). A PNA duplex containing L-lysylamide attached to the carboxy terminus of the PNAAs demonstrates handedness resulting from the helicity of the structure. The source of CD can be attributed to the chiral orientation of the base pairs relative to each other. It has been demonstrated that the induced helicity, as measured by CD, is dependent on the nucleobase sequence proximal center. CD spectroscopy of PNA–DNA and PNA–RNA duplexes provided the first information about the overall base-pair geometry in these complexes. The CD spectra of DNA–DNA and antiparallel PNA–DNA and PNA–RNA duplexes are similar, suggesting that PNA participates in the formation of right-handed helices with a base-pair geometry not much different from that found in a B- or an A-form DNA helix. In contrast, the spectra of parallel PNA–DNA and PNA–RNA duplexes deviate more from the DNA–DNA spectrum, suggesting a different kind of base stacking. CD spectroscopy was also early used to prove the formation of a right-handed PNA–DNA triplex structure. Another important application of CD in this area is the study of the binding of different nucleic acid binding ligands.
PNA AND ITS APPLICATIONS

4.2 Vibrational Spectroscopy

Vibrational spectroscopy is another important spectroscopic method which has been used to study biomolecules for many years. Vibrational spectroscopic studies include infrared (IR), infrared linear dichroism (IRLD) and Raman spectroscopy and, more recently, Raman optical activity (ROA). These techniques are capable of providing important structural information. So far, there has been no representative report related to vibrational spectroscopic studies regarding PNA applications. However, we believe that this particular area of spectroscopy is capable of providing new information related to peptide nucleic acid structure and function. Here, we discuss briefly how these different methods are applied to the study of nucleic acids and try to highlight how they can be made useful for PNA applications.

4.2.1 Infrared Spectroscopy

Infrared spectroscopy is an important tool used to study biomolecules. The IR spectrum of different forms of the same polynucleotides shows large differences in vibrational mixing ratios.
Infrared vibrational circular dichroism (IRVCD) appears to have certain advantages over conventional CD for gaining structural information related to nucleic acids. The IRVCD spectrum can be interpreted in terms of the relative position of the carbonyl groups of the nucleic acid bases and information on base alignment can also be achieved. This technique, if applied to study different complexes of PNA, particularly those containing terminal lysyl residues, might provide valuable information related to the structure and to study certain transitions which are otherwise invisible in electronic CD. IRVCD requires very high concentrations of sample (20–30 mg mL$^{-1}$), a major disadvantage of this application.

### 4.2.4 Raman Spectroscopy

Raman spectroscopy is also a powerful spectroscopic method suitable for use in the conformational study of nucleic acids. The major advantage of this technique over conventional IR spectroscopy is the possibility of carrying out measurements in aqueous solutions. The Raman spectrum of nucleic acids is obtained within the range 600–1800 cm$^{-1}$ and, in general, reflects the same vibrational states of various bonds associated with the conventional IR spectrum. Raman spectra can also be used to detect small (local) conformational changes associated with intermolecular interactions, particularly near the binding sites, using small model systems.

### 4.2.5 Resonance Raman Spectroscopy

Conformational changes in nucleic acids can also be studied using resonance Raman spectroscopy, where excitation in the wavelength range of the electronic absorption of nucleic acid bases is used. A concentration range about 20–100 times lower than in conventional Raman spectroscopy can be used for this kind of study. This method should be suitable for PNA applications, especially to gain information about conformational changes of the bases. Also, structural information related to pure, hybrid or chimeric duplexes or triplex structure of PNAs might be compared with corresponding pure deoxyribonucleotide or ribonucleotide structures to obtain an insight into the influence of the backbone on the individual conformation.

### 4.3 Nuclear Magnetic Resonance Spectroscopy and Mass Spectrometry

In this section we briefly discuss PNA applications of nuclear magnetic resonance (NMR) spectroscopic and mass spectrometric techniques. In mass spectrometry we mainly focus on the use of MALDI/TOFMS to characterize PNA and analyze genetic mutation.

#### 4.3.1 Nuclear Magnetic Resonance Spectroscopy

NMR spectroscopy is probably the most powerful tool to analyze in detail the conformation of oligonucleotides in solution. $^{31}$P-NMR has been widely used to elucidate phosphodiester bond conformation. In proton NMR, in most cases, the two-dimensional nuclear Overhauser effect$^{301}$ has been used to characterize the interproton distances of different parts of the nucleic acid molecule. Consequently, characterizations of different kinds of nucleic acid structures have been carried out. The majority of the work concerning the conformation of various DNA sequences has been done on synthetic oligonucleotides, as high-molecular-weight samples give broad peaks and less good resolution.
NMR spectroscopy has also been successfully applied to determine solution structures of different oligomers, pure and hybrid, of PNA. The monomer exists as both the cis and trans rotamers about the tertiary amide bond, slightly favoring the trans conformation\(^{(20)}\) as revealed from the \(^1\)H spectra. The two rotamers interconvert on the timescale of \(\sim 1\) s at room temperature. For longer sequences, as determined from the \(^1\)H-NMR spectrum of the PNA strand H-GCTATGTC-NH\(_2\), a multitude of structural species can exist. If \(n\) is the total number of residues, then the possible number of structural species will be \(2^n\).

The solution structures of antiparallel PNA–DNA (H-GCTATGTC-NH\(_2\)-5’d[GACATCGC]) and PNA–RNA (GAACTC-5’r[GAGUUC]) duplexes have been determined by \(^1\)H-NMR.\(^{(20,81–85)}\) The PNA–DNA duplex shows a helical conformation with Watson–Crick base pairing scheme. The major groove is wide and deep while the minor groove is narrow and shallow. The helical rise is about 42 Å with approximately 13 base pairs per turn and the helical diameter is close to 23 Å. The carbonyl groups on the backbone base linkers of this structures are oriented along the backbone, pointing in the C-terminal direction. However, the sugar puckering is predominantly in the C2’-endo conformation with all anti-glycosidic torsion angles and trans primary amide bond conformations. The PNA–RNA duplex molecule has features similar to a right-handed A-helix. The carbonyl groups of the PNA backbone linkers are directed towards the C-terminus and primary amide bonds are also in a trans conformation. The nucleic acid strand possesses features very similar to an A-type structure, with C3’-endo sugar pucker and glycosidic torsion angles near \(-160^\circ\).

The structural properties of complexes of PNA are of great interest. However, the information available regarding the structural details has so far been rather limited.

4.3.2 Mass Spectrometry

Mass spectrometers measure the mass-to-charge ratios (m/z) of gas-phase ions. The gas phase is created by different ionization methods, e.g. electron ionization, chemical ionization, fast atom bombardment, electrospray ionization and matrix-assisted laser desorption ionization (MALDI). Mass spectrometry has become an increasingly important tool for the accurate, efficient and fast routine analysis of nucleic acids. It can instantly separate and detect DNA fragments on the basis of their mass-to-charge ratio and, thereby, can allow the determination of DNA length. The MALDI method is a comparatively new method and undoubtedly suitable for high-molecular-weight compounds such as proteins, peptides, DNA/RNA or PNA oligomers. A MALDI spectrum consists of singly charged quasimolecular ions, e.g. [M + H]\(^+\), [M + Na]\(^+\), [M + K]\(^+\), for each sample component. The sample is mixed with a suitable MALDI matrix such as sinapinic acid in a ratio of 1:100. This is allowed to dry on a metal surface. A laser beam is then directed at this surface, causing desorption and ionization of sample components. The development of the MALDI method coupled with time-of-flight (TOF) mass spectrometry has provided an alternative approach to the analysis of nucleic acids.\(^{84,85}\) It has also been successfully employed to study different PNA applications, particularly the characterization of PNA and genetic analysis.

It has been shown that typical matrices, e.g. sinapinic acid, useful for protein study are also suitable for use in PNA studies. PNAs survive the MALDI process intact and are easily ionized. The method holds potential for a rapid evaluation of the purity of a newly synthesized PNA oligomer and provides valuable sequence information regarding the synthesis by-products. It has also been found that dsPNA does not survive the MALDI process under certain experimental conditions.\(^{(29)}\)

MALDI/TOFMS has also been successfully used to study discrimination of single-nucleotide polymorphisms (SNPs) in human DNA using PNA probes.\(^{(30)}\) Human genomic and mitochondrial DNA contain a large number of SNPs that are linked to diseases. Rapid and accurate screening of important SNPs, based on high-affinity binding of PNA probes to DNA, is possible by using MALDI/TOFMS. The captured single-stranded DNA molecules are first prepared by PCR amplification and thereafter hybridized with PNA probes in an allele-specific fashion. MALDI/TOFMS is then used for the rapid and precise detection and identification of the hybridized PNA probes. This provides a very straightforward, rapid, accurate and specific detection of SNPs in amplified DNA. Another powerful feature of this approach is that the direct analysis is made in seconds.\(^{(30,86)}\) Griffin et al.\(^{(87)}\) reported an approach for the detection of multiple point mutations, using allele-specific, mass-labeled PNA hybridization probes following a direct analysis using MALDI/TOFMS. The resultant mass spectra depict peaks of distinct masses corresponding to each allele present. A mass spectral “fingerprint” of each DNA sample is obtained.

4.4 Crystallography and Its Applications

In this section we discuss crystallography and its application in determining the structure of PNA. We also include a few comments in connection with computational studies in PNA structures.
4.4.1 Structure of PNA

The crystal structure of a PNA duplex (H-CGTACG-NH$_2$)$_2$ obtained at 1.7 Å resolution and crystallized in space group P$_{1}$ bar shows both a right- and a left-handed helix in the unit cell.$^{88}$ The helical parameters estimated from this study reveal that the helix is wide (28 Å) and the pitch is large (18 bp) compared with the conventional A- or B-form. The twist, rise, base tilt and displacement values are 19.8, 3.2, 1.0 and 8.3 Å, respectively. One helical turn of PNA duplex is 58 Å long. However, the most important conclusion drawn from the results of the crystallographic study of Nielsen et al.$^{20,89}$ is that they confirm the discovery by Wittung et al.$^{72,73}$ of a PNA–PNA double helix, showing that a sugar phosphate backbone is not a prerequisite for the formation of a nucleobase double helix.

The crystal structure of the PNA$_2$–DNA triplex shows considerable deviations from those of nucleic acid triplexes.$^{89}$ The purine DNA strand undergoes a Watson–Crick base pairing with the homopyrimidine PNA strand in an antiparallel orientation and forms Hoogsteen hydrogen bonds to the second PNA strand of identical sequence running parallel with the DNA. The two PNA strands in the triplex structure resemble the PNA strand in the PNA–DNA duplex. The PNA$_2$–DNA triplex is wide (diameter ~ 26 Å) and the pitch is approximately 16 (triplet). The sugar puckering in the DNA strand is C3'-endo and the backbone torsional angles are similar to those of an A-form structure. The structure is further stabilized through a network of water molecules specifically bound in the minor groove.

4.4.2 Computational Techniques

Molecular modeling and dynamics studies of nucleic acid duplex and triplex structures have complemented the structural information available from NMR and X-ray studies. They have provided potentially useful insights into the three-dimensional conformations of double and triple helical structures. Recent improvements in force field parametrizations and molecular dynamics (MD) algorithms have made a more accurate modeling of nucleic acid (and its mimic) structures possible. With the availability of NMR and X-ray data$^{20,81–83,88,89}$ regarding homo- and hetero-duplex and triplex structures, researchers have been taking interest in different computational studies of PNAs. Sen and Nilsson$^{90}$ reported molecular modeling and dynamics simulation studies on homo- and hetero-duplexes of PNA in aqueous solution under periodic boundary conditions and their results show very good agreement with the respective NMR and X-ray crystallographic data. A MD simulation study of a PNA–DNA–PNA triplex helix in aqueous solution by Shields et al.$^{91}$ gave a certain insight into the conformational flexibility of the structure. It was concluded from energetic analysis that the hybrid PNA–DNA triplex has helical characteristics which are different from those of its actual DNA counterpart. The reason is not simply the replacement of sugar–phosphate by PNA backbones. The definite conformational preferences of the PNA strands influence the driving force behind this conformational flexibility. Srinivasan and Olson$^{92}$ reported a molecular modeling study involving a PNA–DNA–PNA triplex. A total of 12 acyclic torsion angles determine the conformation of adjacent bases in PNA versus nine variables, including the sugar ring, in DNA. Moreover, it was also concluded that the replacement of the sugar ring by a linear bond sequence introduces torsional freedom not present in the nucleic acid. The 12 torsional angles are divided into two groups. The first group, the independent variables, includes torsional angles analogous to the glycosyl and ring torsions of the nucleic acids. The second or the dependent set arises in the successful closure of the PNA backbone.$^{92}$

The information available from these modeling studies, based on predicted structures and cross-examined in terms of the current spectroscopic, calorimetric and crystallographic data, explains why PNA cannot form a very B-like structure.

5 CONCLUSIONS

PNA is a very attractive lead compound owing to its considerable chemical and biological stability and its very specific interactions with DNA and RNA. The application of PNA as a genetic therapeutic agent has to await the development of efficient and safe methods for its cell penetration. However, its application as a recognition molecule has led to promising developments in many areas of chemistry, biology and biotechnology.$^{93,94}$ Continuing efforts in this area of research may yield novel base analogs$^{95–98}$ and provide further applications of this most exciting nucleic acid analog.

Polycyclic Aromatic Compounds Mapping

Dhrubajyoti Chakravarti
Eppley Institute for Research in Cancer and Allied Diseases, Omaha, USA

1 INTRODUCTION

Polycyclic aromatic compounds (PACs) induce tumors by reacting with specific sequences of the initiating oncogene. The resulting DNA damage is converted into oncogenic mutation by in situ mutagenesis during repair or replication. The analysis of PAC/DNA reaction specificity is crucial for understanding the molecular biology of tumor initiation.

The sequence specificity of PAC/DNA reactions has been analyzed by various methods. These methods detect different types of DNA-damage lesions. For example, alkali-labile lesions can be mapped by a chemical procedure (piperidine treatment) and bulky stable adducts can be mapped by a photochemical method (laser-induced strand scission). Biochemical studies have identified several enzymes that act on damaged DNA and can be used for mapping the location of PAC/DNA reactions. For example, DNA lesions block the processive bypass of various enzymes (DNA polymerases, RNA polymerases and exonucleases), whereas endonucleases (UvrABC exinuclease, S1 nuclease and apurinic/apyrimidinic (AP) endonuclease) make lesion-specific incisions. Therefore, the sites of PAC reactions with DNA are mapped by treating PAC-damaged DNA with these enzymes to generate lesion-specific DNA strand breaks that are resolved by denaturing polyacrylamide gel electrophoresis. More recently, various polymerase chain reactions (PCRs) have been developed for mapping the sequence preferences of PAC/DNA reactions in vivo. These techniques include ligation-mediated polymerase chain reactions (LMPCRs), single-strand ligation polymerase chain reactions (SSLPCRs) and terminal transferase-dependent polymerase chain reactions (TTDPCRs). In these methods, the PCR is used to amplify gene-specific DNA fragments generated by chemical or enzymatic DNA lesion processing.

PACs, a group of potent environmental carcinogens found in organic combustion residues, are etiological agents of human skin and lung cancer. These tumors often carry oncogeneally mutated ras genes. To facilitate the study of tumor formation by PACs, model mice suitable for carcinogenesis experiments have been developed. A high number of the tumors that are induced by placing PACs on the backs of these mice are found to contain oncogenic H-ras mutations.

Structure (1) is benzo[a]pyrene (BP); (2) is 7,12-dimethylbenz[a]anthracene (DMBA); and (3) is dibenzo-[a,l]pyrene (DB[a,l]P). All three are widely studied, potent PAC carcinogens. The tumor-forming potentials of PACs are determined by two types of experiments conducted in mouse skin: initiation–promotion and repeated application. In the initiation–promotion experiments, mice are treated once on the skin with a PAC (forming initiated cells) and then with multiple treatments with promoting agents, most commonly TPA (12-O-tetradecanoyl phorbol 13-acetate) to induce the initiated cells into forming tumors. This type of study determines the tumor-initiating potential of the PAC. In the repeated application experiments, mouse skin is repeatedly treated with a PAC. In these experiments, PACs act both as initiators and promoters. Tumors formed from this type of experiment reflect the carcinogenic potential of the PAC. Studies indicate that DB[a,l]P is the most potent carcinogen of all PACs tested so far.

The reaction of PACs with biological macromolecules is necessary for cancer induction. In their environmental forms, however, PACs do not react with biological macromolecules. PACs are oxidized in vivo by cytochrome P450-mediated pathways, a process that has been referred to as metabolic activation. Two major pathways, commonly referred to as the diol epoxide pathway and the radical cation pathway, are involved in the metabolic activation. A third possible pathway (quinone-forming) that may be active for some PACs (such as BP), has also been described. Metabolic activation of the parental PAC generates electrophilic
derivatives\textsuperscript{(12)} that react with DNA, RNA and proteins. Studies have established that PAC/DNA reactions are important in tumor initiation.\textsuperscript{(3,9)}

Various in vitro and in vivo studies have been conducted to investigate the nature of PAC/DNA reactions. These studies indicate that PACs react preferentially with purine bases. PAC reactions with certain sites in DNA bases, such as the N\textsuperscript{2}- of the guanine (Gua) or N\textsuperscript{6}- of adenine (Ade), lead to the formation of bulky adducts that are chemically stable and have therefore been described as \textit{stable adducts}. On the other hand, when PACs react at the N3- or N7- of Ade or at the N3-, N7- or C8- of Gua, the adducts undergo spontaneous hydrolysis of the bond between the purine base and deoxyribose, and have therefore been described as \textit{depurinating adducts}. Both PAC-diol epoxides and PAC-radical cations can form stable and depurinating adducts (for a review, see Cavalieri and Rogan\textsuperscript{(9)}).

The stable adducts and abasic sites formed by the depurinating adducts are pre-mutagenic lesions and are involved in tumor initiation. Table 1 shows a partial summary of our studies that suggest that depurinating adduct formation may be a common characteristic of some potent PAC carcinogens. Specifically, these studies indicate that, for these strong carcinogens, depurinating DNA adducts are stochastically related to the oncogenic, clonal H-\textit{ras} mutations found in mouse skin tumors.\textsuperscript{(5)}

Studies indicate that stable adducts are converted into tumor-initiating H-\textit{ras} oncogenic mutations when cells carrying adducted chromosomes enter the S phase. At this time, replication bypass of adducted bases in the template strand induces base-incorporation errors.\textsuperscript{(14,15)} Research in our laboratory suggests that PAC-induced abasic sites may be converted into mutations by repair errors.\textsuperscript{(13)} Figure 1 shows the proposed misreplication and misrepair models.

PAC treatment on mouse skin often causes local inflammation. This can result in the induction of indirect oxidative DNA damage, including single- and double-strand breaks, formation of abasic sites, and oxidation of DNA bases. Thus, anti-oxidants were found to reduce tumor induction without interfering with stable adduct formation.\textsuperscript{(17)} Research suggests that in PAC-treated mice, oxidative DNA damage (oxidized DNA bases in particular) leads to tumor promotion.\textsuperscript{(18)} Further evidence for a promoting role was obtained from observations that oxidative DNA damage shortens the latency period between adduct formation and tumor appearance.\textsuperscript{(19)}

Experiments to map PAC-reactive sequences in DNA, especially in the H-\textit{ras} gene, can help in the understanding of various early events of tumor initiation. For example, the idea that mutagenesis occurs at the damaged bases in situ would be supported if PAC-reactive hotspot sequences were found to be mutated in preneoplastic tissue. Evidence suggests that stable adducts are

\textsuperscript{b} Data from Chakravarti et al.\textsuperscript{(5)} and from unpublished observations. The oncogenically mutated H-\textit{ras} gene was found to be present in 14–47\% of the cells in papillomas.\textsuperscript{(13)}
Figure 1 Proposed mechanisms for tumor-initiating mutagenesis from PAC-induced DNA damage. The misreplication model shows the formation of a GGC to GTC mutation at H-ras codon 13 from a benzo[a]pyrene-7,8-diol-9,10-epoxide (BPDE) stable adduct. Two rounds of replication are necessary for generating the fixed (double-stranded) mutations. This pathway is thought to occur in replicating cells. The misrepair model shows the formation of H-ras codon 61 CAA to CTA mutation from a DB[a,l]P depurinating adduct-induced abasic site through a single-strand mutation (a T-T mispair) intermediate. The T-T heteroduplex is converted into a fixed mutation by one round of replication. This pathway may occur in resting cells. The fixed mutations are found in initiated cells.

2 METHODS FOR MAPPING POLYCYCLIC AROMATIC COMPOUND – DNA REACTION SITES

2.1 Chemical Methods

The discovery that some of the BPDE-induced DNA damage is "alkali-labile" led to the development of an approach to map the DNA sequence preference for the occurrence of these sites. Studies suggest that the alkali-labile sites may include at least two kinds of DNA damage. These include (a) the rapidly formed abasic sites from labile adducts and (b) the slowly hydrolyzing possible rearrangement derivative of N2-Gua stable adducts. Consequently, this approach has been a popular choice for PAC/DNA reaction site mapping. The alkali treatment often consists of heating PAC-reacted DNA with piperidine at 90°C, which results in DNA strand scission. The piperidine-induced strand scission reaction is an outgrowth of the Maxam–Gilbert sequencing methodology. Investigation of N7-alkylguanines indicates that strand scission reaction occurs as the C8/N9 bond is ruptured and a formamido-pyrimidine structure is formed, which is displaced from the ribose moiety by piperidine. The scission sites are electrophoretically analyzed in an appropriate denaturing polyacrylamide gel.

A majority of the mapping studies have been conducted with BPDE. In these experiments, linear DNA is radio-labeled at one end and reacted with the PAC and then treated with piperidine. These experiments indicate that PACs exhibit a specificity for three-nucleotide-long sequences. For example, Lobanenkov et al. reported that the central G of CGG, TGG, TGT and CGT is the preferred target for BPDE reaction. Similar results have also been reported by other researchers, with Rill and Marsch reporting that the central G of AGG, CGG and TGN is the preferred target for
NUCLEIC ACIDS STRUCTURE AND MAPPING

Figure 2 Piperidine mapping of “alkali-labile” sites induced by anti-BPDE and anti-DB[a,l]PDE in a segment of pBR322 DNA. DNA was linearized with NheI, and the 5’ end was dephosphorylated and then radiolabeled with T4 polynucleotide kinase and γ-32P ATP. The resulting DNA was cleaved again with EcoRI and a 231 bp fragment gel purified to generate one-end-labeled linear DNA molecules. Then 25 ng of labeled DNA was reacted with 5 ng of a PAC diol epoxide in 30 µl reaction solutions containing 15% acetonitrile and 15% ethanol at room temperature in the dark for 3–20 min. Damaged DNA was extracted with chloroform/isoamyl alcohol, precipitated with ethanol and treated with 10% piperidine at 90 °C for 30 min. The fragmented DNA was resolved in an 8 M urea 6% polyacrylamide gel. A + G, Maxam–Gilbert sequencing ladder; no PAC, unadducted, piperidine-treated control.

BPDE reaction. Using this technique, we have studied anti-BPDE- and anti-dibenzo[a,l]pyrene-9,10-diol-11,12-epoxide (anti-DB[a,l]PDE)-reactive sequences in a segment of EcoRI-NheI fragment of pBR322 DNA (Figure 2). In these experiments anti-BPDE was found to react with the central G of GGA sequences and both Gs of CGGC sequences. However, anti-DB[a,l]PDE showed comparatively weaker reactivity and no hotspots in these sequences. It is possible that anti-DB[a,l]PDE-induced DNA lesions are comparatively less alkali-labile.

It has been observed that BPDE lesions can be converted into strand breaks in the absence of alkali treatment, for example when DNA is incubated for extended periods at 37 °C. Bigger et al. reported that when mapping BPDE- and benzo[c]phenanthrene diol epoxide-induced DNA damage, piperidine treatment could be replaced entirely by 24 h incubation at 37 °C. These authors suggested that the strand breaks are formed by depurinating adduct-induced abasic site hydrolysis. However, BPDE induces a relatively small amount of depurinating adducts (1.2% N7Ade and 0.1% N7Gua) and a large amount of stable adducts (98% N2Gua and 0.7% N6Ade). Since the BPDE-induced N7Gua depurinating adducts undergo rapid hydrolysis, the possibility that some of these strand breaks may have been induced by slow hydrolysis of stable adduct lesions cannot be ruled out. BPDE-induced strand nicking is also thought to occur from phosphate adducts. We also observed that in this segment of DNA, the Gs in BPDE-reactive GGA sequences required piperidine treatment for strand breaking, whereas some of the BPDE-reactions with Gs in the CGGC sequences led to strand breaks without piperidine treatment (Figure 3). This suggests that the efficiency of DNA base loss could be determined either by the lability of particular adducts and/or by the sequence context of the adducted base.

Piperidine cleavage patterns may also help with the analysis of stable adduct-induced DNA ultrastructural changes. In these experiments, adducted DNA is first treated with a chemical probe for nucleic acid structure, such as diethyl pyrocarbonate (reacts with syn-purines in Z-DNA or single-stranded DNA), hydroxylamine (reacts with cytosine in single-stranded or distorted DNA).

Figure 3 Liability of sequence-specific BPDE-adduct damage. Mapping experiment conducted as described in Figure 3. No PIP, strand cleavage patterns without piperidine treatment; PIP, strand cleavage with piperidine.
chloroacetaldehyde and bromoacetaldehyde (reacts with A and C in denatured regions and B–Z interfaces) and osmium tetroxide (reacts with thymine residues in distorted DNA such as B–Z junctions).\(^{34}\) Next, the phosphate sugar backbone is cleaved at the level of the adducted bases with piperidine and the resulting fragments are separated in a denaturing polyacrylamide gel. Using this strategy, Bélguise–Valladier and Fuchs analyzed the conformational changes induced by covalently bound N\(^2\)-acetylaminofluorene (AAF) residues to Gua bases in oligonucleotides.\(^{34}\) These experiments revealed that adduct-induced structural deformations extend over 4–6 bases centered around the adduct in both strands, but the nonadducted strand is more extensively distorted.

### 2.2 Photochemical Methods

BPDE-N\(^2\)-Gua stable adducts distort DNA secondary structure.\(^{35,36}\) Irradiation of the adduct complex with laser light at 355 nm results in a specific scission at the adducted base, which results in one single-strand DNA cut at each BPDE-bound base.\(^{37}\) This method has been used to map the sites of BPDE-induced stable adduct formation. In this procedure, the adducted/irradiated DNA is resolved by denaturing polyacrylamide gel electrophoresis.\(^{38,39}\) As can be expected from adduct analysis (98% of BPDE adduct is BPDE-N\(^2\)-Gua), mapping results indicate that BPDE primarily forms adducts at G residues, but 5–10% of the strand scissions were found at A and C residues.\(^{38}\) In general, these experiments indicated that G residues with adjacent G neighbors were preferred as targets over isolated G residues. However, a recent investigation with BPDE-adducted oligonucleotides indicates that a small but significant amount of photochemical strand scission also occurs at neighboring bases, up to 4 bases upstream and 7 bases downstream from the adducted base.\(^{40}\) The bases in the complementary strand were also cleaved, but at 20-fold weaker frequency than the adducted strand.\(^{40}\) Therefore, it is possible that some of the strand breaks in BPDE-induced, irradiated DNA could include such secondary targets.

The analysis of BPDE reactivity to H-ras DNA is of special interest, because of the expected role of site-specific DNA adduct formation in inducing tumor-initiating mutations. Analysis of human H-ras gene exon 1 and 2 sequences indicated that the central G residues of the two oncogenic sites in exon 1 (codons 12 (G GC) and 13 (GG T)) were approximately five times more reactive to BPDE than isolated G residues were.\(^{39}\) BPDE did not show any reactivity towards the central A of oncogenic codon 61 (C AG) sequence in exon 2, but reacted with the G with moderate reactivity.\(^{39}\) If all tumor-initiating mutations induced by BPDE are from stable adducts, these results would predict that BPDE-induced tumors would not contain H-ras codon 61 mutations.

### 2.3 Enzymatic Methods

#### 2.3.1 Processive Enzymes

PAC-induced DNA lesions inhibit the bypass of several types of processive enzymes. These enzymes include DNA and RNA polymerases, and exonucleases. This property has been widely used to construct precision maps of the locations of base lesions in DNA.

**2.3.1.1 DNA Polymerases** Studies indicate that both stable adducts and abasic sites primarily terminate the processive synthesis of DNA polymerases. Bypass synthesis over stable adduct and abasic site lesions occurs relatively infrequently, and in a substantial fraction of these bypassed templates DNA synthesis is erroneous, incorporating noncomplementary bases.\(^{41–43}\) Studies indicate that adduct-induced DNA chain termination is not due to a failure of the 3′–5′ (proofreading) exonuclease activity of DNA polymerases to remove a misincorporated base, but due to the failure of lesion bypass.\(^{44}\) DNA synthesis chain terminations occur opposite the base 3′ to the stable adducted base\(^{45,46}\) or abasic sites\(^{47,48}\) on the template strand. T7 DNA polymerase has been a popular choice for mapping PAC-reactive sites.\(^{47,48}\) In this procedure, often described as primer extension mapping, the primer is radiolabeled at the 5′ end and DNA synthesis is conducted on adducted DNA. Experiments indicate that BPDE reacts mainly with G residues (identified as a synthesis block one base prior to G at the template strand).\(^{48}\) In the rat H-ras gene, BPDE was found to react with moderate specificity with the oncogenic central A of rat codon 61 (CAA).\(^{47}\)

If the adducted DNA can be repeatedly used as a template for DNA synthesis, finer resolution maps will be possible. To take advantage of this possibility, a linear amplification protocol was developed with Taq DNA polymerase.\(^{49}\) While trying to implement this protocol to map PAC/DNA reaction sites, we encountered the problem of a large background from prematurely terminated DNA synthesis. Taq DNA polymerase generates large amounts of incompletely synthesized DNA strands.\(^{50}\) Premature chain termination, however, has not been reported to significantly affect the primer extension mapping procedure. Such premature chain termination is unlikely to be due to differences in DNA polymerase processivity.\(^{51}\) Studies suggest that spontaneous misincorporation resulting in an unextendable 3′ base,\(^{51}\) as well as other factors including the presence of stable secondary structures in duplex DNA that have been noted as “pause” sites for DNA polymerases, could be
involved.\(^{(52)}\) Our studies indicated that efficient proof-reading reduces premature chain termination.\(^{(51)}\)

The following considerations were helpful in developing an efficient linear amplification protocol that allowed full-length chain extension. First, studies suggest that during DNA synthesis, a 5' endonuclease activity associated with the 5'→3' (nick-translating) exonuclease activity of some DNA polymerases helps them to overcome stable secondary structure barriers of strand synthesis.\(^{(53,54)}\) Therefore, conducting DNA synthesis with enzymes that contain this activity may be beneficial for full-length chain extension. Second, it has been suggested that the polymerase activity contained in a DNA polymerase outcompetes other activities associated with the enzyme during DNA synthesis.\(^{(55)}\) We found that when DNA synthesis was carried out with a nick-translating DNA polymerase supplemented with a small amount of proof-reading DNA polymerase, the fidelity of DNA synthesis was greater than when the enzymes were acting singly.\(^{(13)}\) This suggested that such an enzyme combination would provide an effective way of enhancing proofreading activity during DNA synthesis. Accordingly, by using a 8:1 mixture of \(Tth\) and \(Vent\) DNA polymerase, we were able to obtain optimal full-length single-strand DNA synthesis.\(^{(51)}\) We employed this strategy to construct a linear amplification map of anti-BPDE-, syn- and anti-DB\([a,l]PDE\)-reactive sequences in the mouse H-ras exon 2 region. In these experiments, linearized target DNA is linearly amplified with a single 5'-end radiolabeled primer and the reaction products are analyzed in a denaturing polyacrylamide gel. The results indicate that the central A of codon 61 (CAA) reacts with these PACs with moderate specificity (anti-BPDE) and average reactivity (syn- and anti-DB[a,l]PDE) (Figure 4).\(^{(51)}\)

2.3.1.2 RNA Polymerases RNA synthesis by DNA-dependent RNA polymerases is also terminated by DNA adduct lesions. Studies indicate that, like DNA polymerases, T7 RNA polymerase can also occasionally bypass DNA lesions and incorporate noncomplementary bases. One study suggests that when T7 RNA polymerase inserts an incorrect base across the BPDE–N\(^2\)-Gua adduct it leads to premature chain termination, and such a mechanism may contribute to the fidelity of transcription-coupled nucleotide excision repair.\(^{(56)}\) Another study, however, suggests that T7 RNA polymerase can bypass BPDE-N\(^4\)Ade adducts with high efficiency and generate full-length runoff transcripts.\(^{(57)}\) Eukaryotic RNA polymerase III is less able to bypass lesions than T7 RNA polymerase.\(^{(58)}\) The presence of adducts in the template strand is expected, and they are found to be potent terminators of RNA chain growth. It was found that the presence of adducts in the displaced strand could slow down but not terminate RNA chain synthesis by T7 RNA polymerase.\(^{(59)}\)

RNA polymerases have been used to map sites of DNA adduction. In these experiments the target DNA is positioned downstream from a suitable promoter sequence, is treated with PAC from adducts, and runoff transcription reactions are conducted with an appropriate RNA polymerase. T7 RNA polymerase\(^{(55,56)}\) and SP6 RNA polymerase\(^{(48)}\) have been commonly used in these studies.

Essentially similar results have been obtained from BPDE-induced DNA damage mapping experiments conducted either with primer extension reactions with DNA polymerase or runoff transcription reactions with RNA polymerase. For example, BPDE was found to react with G residues in GC boxes.\(^{(60)}\) Since DNA and RNA fragments move differently in sequencing gels, it is difficult to compare the two types of mapping. Nevertheless, Thrall et al. were able to compare BPDE-reactive maps constructed by primer extension by \(T7\) DNA polymerase and by runoff transcription by SP6 RNA polymerase. From these studies they concluded that modified bases that pose relatively strong blocks to DNA polymerase do not always pose a similarly strong block for RNA polymerase. In addition, since different stable adducts were found to block T7 RNA polymerase differently,\(^{(56,57)}\) runoff transcription experiments may yield poor resolution maps compared with DNA polymerase.

2.3.1.3 T4 Exonuclease (3'-Exonuclease Activity of T4 DNA Polymerase) T4 DNA polymerase contains a potent 3'-exonuclease activity that is optimal under nonpolymerizing conditions, such as in the absence of deoxyribonucleotides. The T4 exonuclease activity has been used to map the location of various stable lesions on DNA, including ultraviolet (UV) lesions\(^{(63,64)}\) and BPDE-induced lesions.\(^{(48)}\) In these studies, linear, 5'-end-labeled, adducted DNA is treated with T4 DNA polymerase in an appropriate buffer at 37 °C.\(^{(48)}\) The reaction is terminated by heating to 65 °C for 10 min, and the resulting DNA is desalted by a spin column and resolved in a denaturing polyacrylamide gel.\(^{(48)}\) In this procedure, however, it is difficult to decide on the exact position of the termination of T4 exonuclease, because the templates still contain the adducted base, which influences band migration in the gel. These studies indicate that T4 exonuclease can digest up to 2 or 3 nucleotides prior to the BPDE-adducted base. Unlike DNA polymerases, which progress in the 5'→3' direction, T4 exonuclease progresses in the 3'→5' direction. Therefore, the study of PAC reaction patterns by DNA polymerase and T4 exonuclease can provide important information about the spatial characteristics of adducts in various sequence contexts. Stable adducts are formed either in exocyclic
Figure 4  Linear amplification mapping of anti-BPDE-, syn- and anti-DB[a,l]PDE-reactive sites in mouse H-ras gene exon 2 codon 61 region. (a) A 2 µg sample of a plasmid-cloned H-ras gene (pWT) was reacted with 1 µg of the indicated PAC diol epoxides in the presence of 25% acetonitrile for 15 min at room temperature in the dark. The damaged DNA was extracted by phenol/chloroform and precipitated with ethanol. A 1 µg portion of the template was used in linear amplification reactions and a single 5'-32P end-labeled primer C61F or C61R was used with an 8:1 combination of Tth and Vent DNA polymerase. In this technique, both stable adducts and abasic sites induced by depurinating adducts were mapped as DNA polymerase extension block sites, identified from the termination of extension (one nucleotide 3' to the damaged base) of the complementary strand. The termination events were resolved in a 12% sequencing gel by comparison with the migration patterns of bands generated by enzymatic dideoxy sequencing (G, A, T and C). The gel was read in a PhosphorImager (Molecular Dynamics). Linear amplification was conducted for both strands in this region. The arrow at T in the sequencing gel indicates DNA damage at the central A of codon 61 (CAA). (b) Map of PAC-reactive sites in H-ras exon 2. (c) Mutations identified in H-ras exon 2 (codons 45–66) region induced by anti-DB[a,l]PDE treatment of pWT DNA followed by PCR amplification with either Tth DNA polymerase or an 8:1 combination of Tth and Vent DNA polymerase, as described by Chakravarti et al. Anti-DB[a,l]PDE-reactive bases are indicated by arrows. (Reproduced from Chakravarti et al. by permission of Mary Ann Liebert, Inc.)
or intercalated conformations,\textsuperscript{(20)} which show differential repair activity.\textsuperscript{(21)} Thrall et al. compared maps of BPDE-induced stable adducts by T7 DNA polymerase and T4 exonuclease and concluded that both procedures provide maps of comparable resolution.\textsuperscript{(48)}

2.3.1.4 Exonuclease III Exonuclease III digests DNA processively from the 3’ end. It also contains AP endonuclease activity.\textsuperscript{(65)} This enzyme stalls when it encounters adducted bases and is inhibited from further procession along the DNA strand. When modified DNA thus treated is separated in a sequencing gel, bands are observed corresponding to adduct-bonding sites. In these experiments, 5’-end-radiolabeled, adducted DNA is incubated with exonuclease III at 37 °C.\textsuperscript{(56)} There are no reports of the successful use of this enzyme for mapping PAC/DNA reaction sites.

2.3.1.5 λ-Exonuclease λ-Exonuclease is a highly processive 5’–3’ exonuclease. It is double-strand specific and requires the presence of a 5’-phosphate, and the degradation product is a single-stranded DNA.\textsuperscript{(67)} λ-Exonuclease is blocked by various forms of DNA damage, especially those which significantly alter the double helical structure of DNA. Using this enzyme, the sequence preference of BPDE/DNA,\textsuperscript{(68)} N-acetoxy-N-acetyl-2-aminofluorene (AAAF)/DNA\textsuperscript{(69)} adduct formation has been analyzed. These results indicate that λ-exonuclease is only transiently inhibited by adducts that make small structural perturbation, but is completely inhibited by lesions that induce large changes in duplex DNA, such as BPDE-induced stable adducts.\textsuperscript{(36,68)} Since λ-exonuclease treatment generates truncated DNA that still contains the adducted base, the bands obtained from denaturing polyacrylamide gel are not sharp. The ladders produced by piperidine treatment and λ-exonuclease treatment on BPDE-adducted DNA, however, appeared to be similar, except that the λ-exonuclease ladder appeared to stop 6 nucleotides before the BPDE-induced stable adduct.\textsuperscript{(98)}

Exonuclease III and λ-exonuclease maps of stable exocyclic N\textsuperscript{7}Gua adduct formation by two antitumor antibiotics, tomaycin and anthramycin, have been compared using a map constructed with an endonuclease (UvrABC exonuclease, see section 2.3.2.1).\textsuperscript{(66,70)} The studies suggest that UvrABC exonuclease identifies more adducted sites than either exonuclease III or λ-exonuclease.

2.3.2 Endonucleases PAC/DNA lesion-directed endonuclease cleavage provides another general approach to map the locations of these sites. For a recent review of the DNA structure-selective properties of nucleases, see Suck.\textsuperscript{(71)}

2.3.2.1 UvrABC Exinuclease UvrABC exinuclease is an \textit{Escherichia coli} excision repair enzyme involved in the recognition and the initial incision of a variety of bulky chemical-induced DNA damage reactions.\textsuperscript{(72–74)} UvrABC exinuclease also removes 5’-methylguanine, thymine glycol and abasic sites.\textsuperscript{(75–77)} UvrABC exinuclease has been commonly used for mapping experiments. This enzyme makes two incisions, one on each side of the DNA lesion, to initiate repair. For example, the exinuclease cuts seven nucleotides upstream and four nucleotides downstream to an AAF adduct.\textsuperscript{(78,79)} Similar results were also obtained with BPDE-induced stable adducts (UvrABC exinuclease cuts 6–7 bases upstream and 4 bases downstream of these adducts).\textsuperscript{(80)} In these experiments, radioactively end-labeled adducted DNA is incubated at 37 °C with a mixture of purified UvrA, UvrB and UvrC proteins in the presence of ATP and salts. Reactions are terminated by incubating the reaction mixture with proteinase K and DNA precipitated with ethanol (to remove salts). The resulting mixtures are resolved in denaturing polyacrylamide gels.\textsuperscript{(81)} The DNA sequence context around AAF-adducted Gua residues was found to modulate the relative efficiency of UvrABC exinuclease activity. For example, of three targeted Gua residues in a \textit{NarI} restriction site sequence, one was excised at 77%, another at 45% and the third at 12% efficiency.\textsuperscript{(81)} UvrABC exinuclease, however, was found to cut most BPDE-modified DNA sequences quantitatively, without regard for whether the adducts resided in linear or in supercoiled DNA.\textsuperscript{(80)} Nevertheless, at some BPDE-modified sequences, UvrABC exinuclease could incise only at one side of the adduct.\textsuperscript{(80)} Another possible limitation of the overall efficiency of the procedure is indicated by studies that suggest that UvrABC exinuclease excises only a fraction of the bulky stable adducts present in the templates.\textsuperscript{(82)} Despite the demonstrated usefulness of UvrABC exinuclease in mapping the locations of bulky stable adducts in DNA, such observations undermine this approach.

2.3.2.2 S1 Nuclease The endonuclease activity of S1 nuclease has been tested on BPDE-modified DNA.\textsuperscript{(83,84)} These experiments indicate that S1 cleaves at the local distortions induced by a stable adduct\textsuperscript{(83)} in a non-sequence-specific manner,\textsuperscript{(85)} but with a low efficiency (only 1 in 70 adduct sites are susceptible to S1 cleavage).\textsuperscript{(84)} Studies with BPDE-damaged DNA indicate that S1 is not very active against single lesions but cleaves larger lesions efficiently.\textsuperscript{(86)} S1 nuclease does not cleave discrete abasic sites, presumably because a single abasic site does not sufficiently denature the DNA secondary structure.\textsuperscript{(87)} However, S1 can generate double-strand breaks by cutting through closely clustered abasic sites.
straddling the two strands of DNA.\(^{(87)}\) The single strand-specific endonuclease activity of S1 nuclease would be useful for mapping the locations of DNA damage, but an associated double-strand DNase activity makes the mapping experiments difficult to optimize.

2.3.2.3 Apurinic/Apyrimidinic Endonucleases AP endonucleases can be used to map the locations of PAC-induced abasic site formation (for a review, see Doetsch and Cunningham\(^{(88)}\)). Two major classes of AP endonucleases are known. Class I AP endonucleases (AP lyase) catalyze β elimination reactions at AP sites, leaving 3’ residues. These enzymes also contain DNA glycosylase activity. Class II AP endonucleases, on the other hand, cleave 5’ to the AP site and do not contain an associated glycosylase activity. Mapping with AP endonuclease can provide a map of PAC adduct-induced base depurination sites. In addition, the comparison of maps generated by AP endonuclease and piperidine would be useful for the validation of PAC-induced alkali-labile sites. One study suggests that some alkali-labile sites are indeed AP sites.\(^{(85)}\) Two commercially available AP endonucleases, exonuclease III and endonuclease IV (both class II enzymes), can be used for mapping PAC-induced abasic sites. In these experiments, 5’- or 3’-end-radiolabeled DNA is treated with PAC to form adduct lesions, then incubated with AP endonuclease and resolved in a denaturing polyacrylamide gel. It has been reported that the exonuclease activity of exonuclease III is inhibited in the presence of a citrate buffer,\(^{(89)}\) but we did not obtain great success with this methodology. Treatment of exonuclease III either on circular DNA or on linear DNA with 4-bp 3’ end protrusions\(^{(90)}\) (for exceptions, see Hoheise\(^{(91)}\)), appears to be a better strategy. On the other hand, endonuclease IV does not require any special DNA template preparation and can be used for cleaving the AP sites in a variety of templates.

2.4 Analysis of Mutation Spectra

A large body of evidence indicates that PAC-induced bulky stable adducts as well as abasic sites are premutagenic lesions. Studies indicate that these lesions primarily induce single point mutations. For example, in urr\(^{-}\) (excision repair deficient) bacteria, BPDE treatment (which induces bulky stable adducts almost exclusively, consisting of 98% N⁴Gua and 0.7% N⁶Ade adducts) has been found to induce equal proportions of frame-shift mutations and single base substitution mutations. Of the point mutations, 54% were G to T, 22% A to T and 9% each G to A and G to C changes.\(^{(92)}\) In human cells, BPDE-induced DNA damage was found to induce 60% G to T and 15% each G to C and G to A mutations.\(^{(93)}\) The mutational specificity is thought to be influenced at multiple levels, including the stereochemistry of the adducts, the bases flanking the lesion, and other host cell factors.\(^{(15)}\)

AP sites are thought to be noninstructive. Studies indicate that as DNA polymerases bypass AP sites, purines are incorporated more readily than pyrimidines and dATP is more efficient than dGTP in sustaining chain elongation.\(^{(45)}\) Some studies suggest that the affinity of dATP for template-growing chain-DNA polymerase complex, rather than the differences in the rate of proof-reading excision, is responsible for the preferential A insertion across AP sites (A-rule).\(^{(94,95)}\) The A-rule has been verified for both spontaneous and induced depurination. For example, the major form of spontaneous base loss in vivo involves Gua depurination.\(^{(96)}\) Correspondingly, the most common mutation was G to T changes.\(^{(97)}\)

In addition, aflatoxin B1, which induces a major N⁷Gua depurinating adduct, also induces a high proportion of G to T mutations.\(^{(98)}\) In E. coli, >50% of abasic site-induced mutations are A to T transversions.\(^{(43,97,99)}\) In human cells, abasic sites were found to induce a majority (40%) of frame-shift deletions along with 30% G to C and approximately 15% each A to G, A to C and A to T mutations.\(^{(100)}\)

The preponderance of single point mutations over multiple mutations induced by these types of PAC-induced DNA damage makes the analysis of mutational spectra a possible way of identifying PAC/DNA reaction sites. However, this approach is inefficient, and for reasons discussed previously would provide a low-resolution analysis of the PAC/DNA reaction. Nevertheless, mutational analysis can be used as complementary evidence for mapping experiments by more direct methods (Figure 4c).\(^{(51)}\)

2.5 Mapping DNA Damage Induced In Vivo

One of the chief reasons for designing PAC/DNA lesion mapping experiments in vivo, is to understand whether the sequence context of a particular DNA damage contributes to the proficiency of its repair. This goal is conveniently accomplished by mapping DNA damage sites in target genes at different times. Three PCR-based methods, namely LMPCR (for a review, see Pfeifer et al.\(^{(101)}\)), SSLPCR\(^{(102)}\) and TTDPCR\(^{(103)}\) have been developed for these purposes. Figure 5 shows flow diagrams of these methods.

2.5.1 Ligation-mediated Polymerase Chain Reaction

In this method, chromosomal DNA is extracted at various times after treating cells with DNA damaging agent. It is then digested with a restriction enzyme, followed by a mapping treatment to generate strand breaks at or near the damage site. The strand breaks create a ligatable 5’
end. For example, to map UV (6–4) photoproduction lesions, which are alkali-labile, DNA is treated with piperidine and, to map BPDE-induced stable adduct lesions, DNA is treated with UvrABC exonuclease. Although the site of UvrABC exonuclease excision at the 5’ side of a BPDE adduct is variable (6–7 bases), this enzyme always cuts after 4 bases on the 3’ side. The 3’ incision is relevant to LMPCR. Recently, a LMPCR method to map aflatoxin B1-induced DNA depurination has been reported, in which the strand breaks are induced by treating damaged DNA with piperidine. Alternatively, abasic site-specific DNA strand breaks can be induced by treating DNA with an AP endonuclease. Next, a gene-specific primer is annealed and extended with T7 DNA polymerase (Sequenase). This creates a pool of variously sized, double-stranded products that are blunt-ended at the 3’ end.

An unphosphorylated, asymmetric double-stranded linker is then ligated to the blunt end of the extended products and a PCR amplification reaction is conducted with a linker-specific primer and a nested gene-specific primer. The PCR products are resolved in a denaturing polyacrylamide gel. The LMPCR amplified break positions are detected either by radio-densitometry in a PhosphorImager (Molecular Dynamics, CA, USA) or by electroblotting the gel onto nylon membranes and hybridizing with a gene-specific probe. Comparison of BPDE/DNA reactive sites in vitro with corresponding LMPCR maps suggests that, in general, BPDE reacts with DNA with similar sequence specificity both in vivo and in vitro.

LMPCRs can detect a relatively small population of damaged DNA. Studies suggest that a population of 100 molecules of template DNA and a lesion population more than 1 in 10,000 nucleotides, is adequate for such analysis. It has been reported that the LMPCR technique could be made more sensitive by electrophoretically enriching restriction enzyme-digested chromosomal DNA to the size of the target gene. In a variation of the basic LMPCR protocol, biotinylated primers have been used for the initial gene-specific extension, and subsequently biotinylated, linker-ligated molecules have been purified with streptavidin. However, it is not known whether such changes help the LMPCR protocol. Nevertheless, several steps of LMPCRs could contribute to inefficient band detection.

Figure 5. PCR methods for mapping PAC/DNA reactions in vivo. The PCR products are resolved in sequencing gels. When PCR is carried out with one of the primer’s 5’ ends radiolabeled, the bands are detected by autoradiography. Alternatively, the electrophoresed DNA is blotted onto nylon membrane and bands visualized by hybridization with gene-specific probes. P, phosphate; A, amine; B, biotin.
For example, the 5’ end generated by the strand scission reaction must be phosphorylated and also the primer extension reactions must be full-length in order for blunt-end linker ligation reaction to occur. In addition, the efficiency of blunt-end ligation may determine the effectiveness of the protocol. Although the ligation kinetics of the variously-sized double-strand fragments could possibly vary, it is unlikely that individual templates will be selectively lost in order to become under-represented in steps up to linker ligation. The final PCR amplification can only compensate for the loss of uniform signal strength.

2.5.2 Single-strand Ligation Polymerase Chain Reaction

SSLPCRs differ from LMPCRs by not requiring DNA damage-specific strand cleavage. Instead, the method depends on the DNA polymerase-blocking properties of various DNA lesions. A second difference in this protocol is the use of single-strand ligation reaction with T4 RNA ligase. In this method, chromosomal DNA is isolated from damaged cells and subjected to linear amplification with a biotinylated primer specific for a target gene. Gene-specific linear amplification enhances the overall resolution of the procedure. This results in the formation of a population of single-stranded DNA molecules that are truncated by damage-induced termination of DNA synthesis. The biotinylated single-strand DNA is captured with streptavidin and separated from free genomic DNA by washing. Using T4 RNA ligase, these molecules are ligated to a single-strand linker DNA (containing a 5’ phosphate for ligation and a 3’ amine to prevent self-ligation). Using a two-step PCR with an oligonucleotide complementary to the linker sequence (to act as the forward primer) and a 5’-end-radiolabeled second primer (nested to the linear amplification primer), one-strand radiolabeled PCR products are generated. These products are denatured by heating to 95 °C in a formamide-containing sequencing gel loading buffer and resolved in a denaturing polyacrylamide gel. Although SSLPCRs are likely to be very useful, this method has yet to be used for mapping PAC-reactive sites in DNA.

The use of T4 RNA ligase may limit the sensitivity of SSLPCRs. DNA is not a preferred substrate for T4 RNA ligase and ligation proceeds in a slow and inefficient manner, using low amounts of single-stranded DNA. It has been reported that SSLPCRs gave weaker intensity bands than LMPCRs.

2.5.3 Terminal Transferase-dependent Polymerase Chain Reaction

TTDPCRs were designed to overcome the perceived deficiencies of LMPCRs. Like SSLPCRs, TTDPCRs also use linear amplification with a gene-specific primer, relying on the polymerase-blocking property of the DNA lesion for synthesizing truncated single-strand molecules. Next the single-stranded DNA molecules are ribo-tailed with terminal deoxynucleotidyl transferase (TdT) using rGTP. The use of ribonucleotide in this reaction limits the tailing to a few residues (an average of three nucleotides). Next, a double-stranded linker containing a 3’ overhang of three complementary cytosines is ligated with T4 DNA ligase. The complementary oligonucleotide of the linker contains a 5’ phosphoryl and 3’ (aminopentyl) blocking group. This ligates the recessed 5’ end of the linker with the 3’ rG tail of the linear amplified molecules. The cohesive-end ligation in TTDPCRs may be more efficient than the blunt-end ligation of LMPCRs. Next, the linker-ligated templates are PCR amplified with a nested gene-specific primer and the top oligonucleotide of the linker. The products are resolved in a denaturing polyacrylamide gel, electroblotted and hybridized with an internal gene-specific probe as in LMPCRs. UV-induced DNA damage has been mapped by TTDPCRs and LMPCRs in parallel. TTDPCRs were reported to yield approximately 4–7 times stronger bands than LMPCRs.

LMPCRs are the older method and have found wide acceptance. In comparison, SSLPCRs or TTDPCRs are recently described methods. Both SSLPCRs and TTDPCRs are likely to be useful procedures for mapping the sequence preferences of various types of carcinogen-induced DNA damage.

1 INTRODUCTION

The PCR entails the in vitro enzymic exponential amplification of a specific DNA sequence from a complex mixture. Increasing the copy number of a target nucleic acid sequence greatly facilitates its detection. The method involves repetitive bidirectional synthesis of a segment of double-stranded DNA occurring in successive rounds (thermocycling) in such a way that the product of one round serves as a template for the next round. Exponential amplification of specific RNA sequences is achieved by the reverse transcription polymerase chain reaction (RT-PCR). PCR can be adapted to allow quantification of a target DNA or RNA sequence originally present in the sample prior to amplification. PCR provides sensitivities which are order of magnitudes greater than Southern and Northern analysis and nuclease protection assays. Due to its extraordinary sensitivity, the PCR is the method of choice for detection of nucleic acids at very low levels. PCR has greatly facilitated the detection of inherited mutations associated with genetic disease. It has also found widespread application in the detection of infectious agents in a variety of clinical and environmental samples. Conventional means for identification
of pathogens include immunoassays for viral antigens or antiviral antibodies in the serum of patients and, in many cases, tedious and time-consuming culturing techniques that often lack the sensitivity and specificity required for routine diagnosis. PCR-based detection assays are simpler and offer much higher sensitivity and specificity. LCR, 3SR, NASBA and SDA are alternative exponential amplification systems. LCR is especially useful in mutation detection. Contrary to PCR and LCR, in 3SR, NASBA and SDA the exponential amplification is achieved in an isothermal manner. The high sensitivity of the exponential amplification techniques calls for extreme caution to avoid contamination of the samples from amplified sequences.

2 POLYMERASE CHAIN REACTION

2.1 Simple Polymerase Chain Reaction

The PCR, one of the most powerful techniques used in nucleic acid analysis and molecular biology today, was invented by Kary Mullis who won the 1993 Nobel Prize in Chemistry for this contribution.

The principle of PCR is illustrated in Figure 1. In PCR, successive rounds (cycles) of heat denaturation, primer annealing and primer extension by a DNA polymerase result in a repetitive bidirectional synthesis of a segment of double-stranded DNA, the end result being an exponential increase in the number of target DNA copies. The sequence amplified by PCR is determined by the position of the primers. In the first heating step (95°C), the double-stranded DNA is denatured to form two single strands (disruption of hydrogen bonds). The temperature is then reduced to between 40 and 72°C, thereby allowing the binding of two oligodeoxynucleotide primers (upstream and downstream) to complementary sequences on opposite strands of the target DNA fragment. The primers are oriented so that their 3’ ends point toward one another along the intervening sequence. The final temperature change of the cycle (to 72°C) allows the 5’ → 3’ extension of each primer catalyzed by DNA polymerase. Following one complete cycle, two copies containing the sequence of interest are generated. As the cycling continues, the primers bind to the original target as well as to the newly synthesized strands and the number of target DNA copies approximately doubles at every cycle. The short products, which accumulate exponentially during PCR, are of uniform size corresponding to the distance between the 5’ ends of the two primers. The theoretical abundance of the short products is $2^n$ where $n$ is the number of cycles performed. This translates to approximately one million times amplification in 20 cycles of PCR. The strands that are synthesized as copies of the original template (long products) are bounded at their 5’ end by a primer while their 3’ end is determined by the position at which the DNA polymerase stops. Strands containing undetermined 3’ termini can be generated only by copying the original template and therefore their accumulation is linear $(2n)$. As a consequence, the long products are rare compared to the short product. The size and homogeneity of the PCR product can be assessed by agarose gel electrophoresis and ethidium bromide staining or by Southern blot and hybridization to labeled probes.

The earliest PCR experiments used the Klenow fragment of E. coli DNA polymerase I at a temperature optimum of 37°C, but this enzyme was easily inactivated at the high temperatures required for DNA denaturation and therefore fresh aliquots had to be added in each cycle. One of the most important developments in PCR was the introduction of Taq DNA polymerase, a thermostable DNA polymerase (temperature optimum at 72°C) originally isolated from the thermophilic bacterium Thermus aquaticus (Taq) which lives in hot springs. The
availability of Taq DNA polymerase has greatly simplified
the automation of PCR since the enzyme is added only
once, at the beginning of the reaction.\(^4\) Furthermore,
the use of Taq DNA polymerase has enhanced consider-
ably the specificity and yield of the amplification process
because it allowed the primer annealing and extension to
occur at higher temperatures, thus minimizing competing
mispriming events (annealing to nontarget sequences).
The Taq DNA polymerase has no 3' → 5' exonuclease
activity (proofreading activity) but it possesses 5' → 3'
exonuclease activity during polymerization.\(^5\) In situa-
tions where the PCR product is to be sequenced or
sub-cloned for expression studies, the fidelity of the ampli-
fication is also crucial. Thermostable proofreading DNA
polymerases (e.g. Pfu DNA polymerase) have become
commercially available for these purposes.

The selection of primers is a key factor in determining
the success of specific amplification. Primers are usually
20–28 bases long to permit high-stringency annealing,
thus providing greater specificity. Shorter primers will
yield nonspecific products and much longer sequences will
result in low yield. Whenever possible, the two primers
should have very similar melting temperatures to ensure
that a given thermal profile is optimally efficient and
specific for both primers. The G + C base composition
should be about 40–60%. Intrastrand complementary
regions resulting from runs of three or more G and C are
inclined to form secondary structures (e.g. hairpin loops)
and thus should be avoided especially at the 3' end of
the primer. Interstrand complementary regions at the 3' ends
of the primers should also be avoided in order to prevent
the formation of primer dimers. This amplification artifact
is a double-stranded DNA fragment whose length is equal
to the sum of the two primers and appears to occur when
one primer is extended by the polymerase over the other
primer. Computer programs are available to aid in the
process of primer selection. Primers are added in excess
so that they do not become the rate-limiting factor in
the reaction. The primer concentrations used range from
0.05 to 0.5 μmol L\(^{-1}\). High concentrations may promote
mispriming and the formation of primer dimers.

Since DNA polymerase extends the 3' end of the
primer, the 5' end can be altered to create modified
PCR products differing from the starting template. This
provides a means of introducing restriction sites, spec-
ific mutations, promoters and regulatory elements (for
subsequent expression). These sequences, although not
complementary to the target DNA, become effectively
incorporated into the final product. In a similar manner,
various affinity tags or labels may be attached to the 5'
end of the primers and get incorporated into the newly
synthesized strands to allow the capture and detection of
the amplification products.\(^6\)

Each of the deoxyribonucleoside triphosphates (dATP,
dTTP, dCTP, dGTP) are usually present in the PCR
mixtures at a concentration of 20–200 μmol L\(^{-1}\). Higher
concentrations are avoided because they promote mis-
priming at nontarget sequences (decreased PCR speci-
ficity) and misincorporation of nucleotides (decreased
fidelity of DNA synthesis). The four dNTPs should be
used at equal concentrations to avoid misincorporation.
Like the primers, affinity tags or labels may be attached
to the dNTPs and become incorporated into the ampli-
fication products for subsequent capture and detection.
Mg\(^{2+}\) is bound to the dNTPs and is required for optimal
activity of the polymerase. The Mg\(^{2+}\) concentration may
affect the primer annealing, the denaturation tempera-
ture, PCR specificity and yield and therefore it should be
optimized for each target DNA.

The inherent specificity of PCR lies in the fact that
in order for exponential amplification to occur both
primers must anneal, in the correct orientation, to a
relatively short target DNA sequence. Moreover, after
a few cycles of amplification the amount of target DNA
has increased so much that less favourable competing
events progressively become less frequent. The specificity
of PCR may be improved further by increasing the
annealing temperature and optimizing the incubation
times for annealing and extension, to reduce the chances
for mispriming and extension of nontarget sequences.
The denaturation time and temperature should be long
enough to allow complete separation of the DNA strands
in each cycle, thus ensuring high yield.

A practical approach used widely to minimize the
nonspecific amplification and the formation of primer
dimers involves the addition of an essential reagent (e.g.
DNA polymerase, primers, dNTPs or template) to the
reaction mixture after it has reached high temperature,
i.e. >80°C (“hot-start” protocol).\(^7\) Alternatively, the
“hot-start” protocol may be performed by using a wax
or jelly barrier that melts and permits mixing of aqueous
components at a high temperature.\(^8\) Another approach
to “hot-start” PCR uses a monoclonal antibody that
binds to and inactivates the Taq DNA polymerase at
ambient temperature. This inhibition is reversed when
the temperature is raised in the denaturation step of the
first cycle and the enzyme functions normally during the
course of PCR.\(^9\)

The theoretical amplification of PCR (2\(^n\)) would
be achieved only if the reaction could be performed
with 100% efficiency (i.e. doubling of the DNA in
each cycle). In practice, however, the system operates
at a lower efficiency mainly as a result of an initial
(lag) phase. This is attributed to a number of factors
including the unavailability of the DNA target due
to strand breaks, lack of its dissociation from other
macromolecules, structural constraints, or a tendency of
the long parental strands to reanneal. A low efficiency during the first few cycles of PCR greatly compromises the overall yield of the reaction. Once the lag phase is overcome, the reaction enters the exponential phase. During late PCR cycles, however, the exponential rate of product accumulation decreases, a phenomenon commonly referred to as the “plateau phase” of PCR. The point at which the amplification reaches a plateau depends primarily on the amount of input target DNA and the number of cycles. The factors contributing to the plateau effect include competition between primer/template and template/template annealing, incomplete denaturation of the target strands and competition for reactants by any accumulated nonspecific products. Depletion and/or destruction at high temperatures of PCR reactants, such as primers, dNTPs and polymerase, as well as inhibition of PCR by end-products of the reaction, such as pyrophosphate, may also contribute to the plateau effect. The plateau phase is an unavoidable occurrence inherent to the technique.

The exquisite sensitivity resulting from the exponential amplification in PCR renders it highly vulnerable to contamination of a sample by-product carried over from previous amplifications. Vigorous precautions must therefore be taken to avoid the setbacks associated with spurious amplifications. Some of the common practices exercised in most PCR-performing laboratories include pre-aliquoting of reagents, use of dedicated pipettes and physical separation of the areas in which PCR samples are prepared, amplified and detected. Ultraviolet irradiation of reagent, buffers, pipettes, pipette tips and glassware is also common. Finally, the inclusion of negative (no target DNA) and positive controls in all experiments is essential for the accurate interpretation of results. The generation of false positives is a serious concern when PCR is used for diagnostic purposes.

An elegant approach used to minimize contamination involves the selective degradation of PCR product carryover. Deoxyuridine triphosphate (dUTP) is added instead of dTTP in the PCR mixture and it is thus incorporated into the amplification products. If contamination is suspected, the enzyme uracil N-glycosylase (UNG) is added to the reaction mixture prior to thermal cycling. UNG catalyzes the excision of uracil from any potential single- or double-stranded carryover DNA (but not RNA) present in the reaction mixture prior to the first PCR cycle. The resulting abasic polynucleotides are susceptible to hydrolysis in slightly alkaline solutions (such as the PCR buffer) and elevated temperature and therefore cannot function as templates. Since UNG itself is inactivated at the high temperatures used in PCR, the amplification products generated during thermal cycling are not destroyed and can accumulate as usual. The amplified DNA can still be assayed by hybridization with complementary probes.

2.2 Nested Polymerase Chain Reaction

Nested primer PCR is a variation of PCR used to increase the specificity and sensitivity of amplification. This protocol uses two sets of primers, one set internal to the other, and amplification takes place in two PCR steps. The first PCR uses the outer set of primers to enrich the sample with the sequence of interest. The product serves as a template for a second PCR using the inner set of primers to generate a more homogeneous final product. The disadvantage of this approach lies in the potential of contamination associated with opening the reaction tube, dilution (to decrease the concentration of the outer primers) and addition of the inner primer set. It is possible to perform nested PCR in a single reaction tube without dilution, in the presence of both primer pairs. This is achieved by designing the outer and inner primers to have different melting temperatures. During the first cycles only the outer primers are used and subsequently the denaturation and annealing temperatures are adjusted to allow only the inner primers to anneal.

2.3 Long Template Polymerase Chain Reaction

The amplification of long fragments from genomic DNA has been a problem when using standard PCR conditions and Taq DNA polymerase. The size of PCR products generated with Taq DNA polymerase is limited to about 2 kbp. It was found that combining the high processivity of Taq DNA polymerase with the proofreading accuracy of another thermostable DNA polymerase in a PCR allows amplification of much larger DNA templates (up to 50 kbp).

2.4 Multiplex Polymerase Chain Reaction

Multiplex PCR entails the simultaneous amplification of several target DNA sequences (e.g. several regions of a large gene) in a single PCR. A unique pair of primers is designed for each target sequence. It is necessary that the primer pairs have close melting temperatures in order to avoid large variation in the amounts of amplified products. Multiplex PCR is more useful when the various target sequences exist in similar numbers in the sample. It has been applied to the diagnosis of genetic disease (e.g. muscular dystrophy), pathogen identification and forensic assays.

3 REVERSE TRANSCRIPTION POLYMERASE CHAIN REACTION

Amplification of specific RNA sequences can be accomplished by first generating a complementary copy of DNA
(cDNA) with reverse transcriptase. RT-PCR has been an invaluable analytical tool for studying gene expression, monitoring various infectious agents and diagnosis and monitoring of disease. Random hexamers, oligo-(dT) or the downstream PCR primer may be used as primers for the reverse transcription. The other PCR primer anneals to the generated complementary DNA strand and Taq polymerase synthesizes double-stranded cDNA which is further amplified in the usual way. The Moloney murine leukemia virus (MMLV) and the Avian myeloblastosis virus (AMV) reverse transcriptases are widely used in RT-PCR. When amplifying RNA it is essential to remove the DNA present because it may serve as a template in PCR using the same primers. Undesirable target DNA should be degraded enzymically using deoxyribonuclease I. In the case of amplification of eukaryotic mRNA, the primers should be derived from separate exons so that PCR products arising from DNA are much longer, and in lower yield, because they contain intron sequences.

3.1 One-step Reverse Transcription Polymerase Chain Reaction

In this method both the reverse transcription and PCR are performed in one step (coupled) by using optimized buffer and one (or combination of) thermostable reverse transcriptase/DNA polymerase. RNA templates containing secondary structures are often difficult for viral reverse transcriptases to reverse-transcribe. The thermostable reverse transcriptases (e.g. Tth DNA polymerase) are able to synthesize cDNA at high temperatures that destabilize the secondary structures, thus providing increased sensitivity and specificity.

4 METHODS FOR ANALYSIS OF POLYMERASE CHAIN REACTION PRODUCTS

The most commonly used method for analysis of PCR products is based on the electrophoretic separation of the DNA followed by staining with the intercalating fluorescent dye ethidium bromide. Quantification of the amplified DNA may then be carried out by taking the negative of a picture of the stained gel followed by scanning densitometry. Appropriate DNA markers are required in order to construct the calibration curve. The dependence of the amount of bound ethidium on the length of the DNA fragment should be taken into account when constructing a calibration curve. A major disadvantage of this method is its limited sensitivity (10 ng). Silver staining in conjunction with polyacrylamide gel electrophoresis provides higher sensitivity.

A more sensitive approach is based on the incorporation of radioactive dNTPs (labeled with $^{32}$P) directly into the amplification products and detection by autoradiography of dried gels or membranes to which the products have been transferred (Southern blot). Alternatively, dNTP modified with nonradioactive labels (e.g. biotin or hapten) can be incorporated in the amplified DNA through PCR. The modified dNTP should be stable during thermal cycling. Following PCR, the mixture is electrophoresed and the fragments are transferred to a nylon membrane. The DNA is then detected by reacting with alkaline phosphatase or horseradish peroxidase conjugated to (strept)avidin. The substrates used give a color or fluorescent precipitate at the position at which the DNA is immobilized. The concentration of a modified (nonradioactively labeled) dNTP in the PCR mixture may have a significant influence on the activity of DNA polymerase. Thus, both the modified and unmodified dNTP (at an optimal ratio) should be included in the PCR mixture to ensure efficient incorporation and high yield.

High-performance liquid chromatography (HPLC) with anion-exchange columns and absorbance monitoring at 260 nm has been used successfully for separation and determination of PCR products. The reaction mixture can be injected onto the column directly without prior purification.

Capillary electrophoresis has been established rapidly as an efficient method for quantitative analysis of PCR products. The system consists of two electrolyte chambers connected with a separation capillary. Capillary electrophoresis is an easily automatable and rapid technique that provides qualitative and quantitative results with high resolution and low sample/reagent consumption.

A more sensitive approach is based on the incorporation of radioactive dNTPs (labeled with $^{32}$P) directly into the amplification products and detection by autoradiography of dried gels or membranes to which the products have been transferred (Southern blot). Alternatively, dNTP modified with nonradioactive labels (e.g. biotin or hapten) can be incorporated in the amplified DNA through PCR. The modified dNTP should be stable during thermal cycling. Following PCR, the mixture is electrophoresed and the fragments are transferred to a nylon membrane. The DNA is then detected by reacting with alkaline phosphatase or horseradish peroxidase conjugated to (strept)avidin. The substrates used give a color or fluorescent precipitate at the position at which the DNA is immobilized. The concentration of a modified (nonradioactively labeled) dNTP in the PCR mixture may have a significant influence on the activity of DNA polymerase. Thus, both the modified and unmodified dNTP (at an optimal ratio) should be included in the PCR mixture to ensure efficient incorporation and high yield.

A fully automated instrument for PCR amplification and analysis of the products was developed. The sample was automatically loaded, sealed, cycled in a rapid air thermal cycler and injected onto a gel filtration column for removal of salt and dNTPs followed by analysis of amplified DNA by capillary electrophoresis. A noncross-linked polymer-filled capillary was employed with automatic refilling. Detection was accomplished by laser-induced fluorescence.

The approaches described above detect all PCR products, specific and nonspecific. PCR products from clinical samples often appear on the slab gel as a number of bands, thus making difficult the identification of the correct size. Therefore, confirmation of the sequence of the specific product is usually required. This is accomplished by hybridization of the amplified DNA with complementary probes. Unlike ethidium bromide staining or direct labeling of PCR products, hybridization demonstrates the presence of the specific DNA band only.
